

ABSTRACT

CANTARA, WILLIAM ANTHONY. Arginyl-tRNA Modifications Modulate Anticodon Domain Structure, Function and Dynamics in *Escherichia coli*. (Under the direction of Paul F. Agris)

During ribosome-mediated protein synthesis, non-initiator tRNAs act as translating chaperones by transferring the correct amino acid to the ribosome through sequence-specific interactions with mRNA codons in the ribosomal A-site. To achieve uniformity in codon recognition ability between different tRNAs, the anticodon domains of all must adopt a singular conformation in the ribosomal decoding center. Since there is a necessary sequence variation for the three anticodon residues, innovative ways of attaining a constant loop structure are required. Nature has resolved this issue by introducing functional groups to the loop residues, changing the chemical environment and, thus, the conformation. In fact, there is a large diversity and number of these modifications found in tRNAs of all known life.

Escherichia coli (*E.coli*) arginyl-tRNAs offer the opportunity to study these modifications in the context of six-fold degenerate codons that vary widely in their cellular usage. A single set of very similar isoacceptors, tRNA^{Arg1}_{ICG} and tRNA^{Arg2}_{ICG}, have anticodon domains that differ only in the presence or absence of a very rare modification, 2-thiocytidine (s^2C_{32}). These tRNAs are particularly interesting not only because of the rare s^2C_{32} modification, but also through the wobble position modification I₃₄, they are both responsible for decoding two very common codons CGU and CGC as well as the very rare CGA codon. Typically, the codon usage correlates with the tRNA content of the cell; however, in this instance, the tRNA content is high which does not match what would be expected for an isoacceptor that recognizes a rare codon. Here we have shown conclusively that modifications can act to restrict the decoding capability of the tRNA to only the two common codons, suggesting that the tRNA is present at high levels, consistent with decoding common codons, but that there is a smaller pool of tRNA in different states of modification, corresponding to decoding of the rare codon. The mechanism of this function is not completely understood, however, we show that the modifications do not accomplish this through a completely structural device. In this case, modifications act to modulate the flexibility of specific loop residues, thereby

modulating the conformational landscape that must be traversed between two disparate, but necessary, cellular conformations.

It is clear from many previous studies that modifications can perform specific functions in the anticodon stem and loop (ASL), most notably at position 34 which is known to facilitate the “wobble” recognition of multiple codons. *E.coli* tRNA^{Arg4}_{UCU} offers a novel function of modification at this position that is not fully understood. In a very similar isoacceptor, partially modified tRNA^{Lys}_{UUU}, a very different decoding function is seen. Both of these tRNAs contain the same loop sequence with the exception that tRNA^{Arg4}_{UCU} has a C at position 35, whereas tRNA^{Lys}_{UUU} has U₃₅. Interestingly, they both contain the same loop modifications, mnm⁵U₃₄ and t⁶A₃₇, with the exception that tRNA^{Arg4}_{UCU} has an additional s²C₃₂ modification; however tRNA^{Lys}_{UUU}, in this particular modification state can decode both AAA and AAG and tRNA^{Arg4}_{UCU} decodes only AGA. Although s²C₃₂ enhances codon discrimination in tRNA^{Arg1}_{ICG}, codon-specific ribosome binding assays clearly refute this role in tRNA^{Arg4}_{UCU}. The modifications, however, appear to impart similar biophysical and thermodynamic properties to the ASL as in tRNA^{Lys}_{UUU}, therefore a full structural characterization is underway using NMR spectroscopy to ascertain whether modifications drive the conformation toward a canonical U-turn conformation as with tRNA^{Lys}_{UUU}. Preliminary evidence indicates a role for modifications in altering the stability of the non-canonical C₃₂•A₃₈ base pair through stable stacking interactions and elevation of A₃₈H1 pKa.

Arginyl-tRNA Modifications Modulate Anticodon Domain Structure, Function and
Dynamics in *Escherichia coli*

DEDICATION

To Shraddha, my loving wife, who keeps me on the right path through life and is someone that I can always count on. Also, to my mother and other family members for their sacrifices throughout my life and for nurturing my curiosity. Finally, to my friends and labmates for their support and advice.

BIOGRAPHY

William Anthony Cantara spent part of his childhood in York, Pennsylvania until moving to Grassflat, Pennsylvania during kindergarten. He spent his childhood and high school years enjoying rural life and participating in athletics. He attended Juniata College, where he met his wife and graduated with a bachelor's degree in Biochemistry and Physics. During college, his lab experiences with Dr. Jill Keeney showed him that research was his true calling. He then moved to Raleigh, NC with his future wife to work under the guidance of Dr. Paul Agris at North Carolina State University. Will looks forward to using the skills and experiences he has gained over the past five years to lead a successful career as an independent researcher.

ACKNOWLEDGEMENTS

First, I would like to express gratitude to my advisor, Paul F. Agris, for helping me to develop into a researcher. His mentoring and discussions about the inner workings of a lab and research facility have opened my eyes to the nuances that must be considered when starting a lab and the joys associated with the process. Also, my advisory committee has offered meaningful insights and knew how to offer constructive criticism to ensure that my projects were comprehensive. In particular, I acknowledge the willingness of E. Stuart Maxwell for opening his lab to me during my first year and offering his graduate student, Keith Gagnon, to teach me cloning techniques. I extend gratitude to the faculty, staff and graduate students of the Department of Molecular and Structural Biochemistry at North Carolina State University and the Life Sciences Building at the University at Albany for their friendship, advice and willingness to offer their expertise.

No acknowledgement would be complete without noting the contributions of current Agris lab members and alumni. I would like to specifically thank William Graham, Franck Vendeix, Estella Gustilo, Yann Bilbille and Kun Lu for their hard work and contributions to my projects. I would also like to thank the undergraduates that I have had the opportunity to mentor and have assisted with various aspects of my projects: Jia Kim, Minhal Makshood and Erick Harr. My friendships and experiences over the past five years with members of the Agris lab in both Raleigh and Albany have shaped who I am as a researcher and I owe a great deal of my successes to them.

Finally, I thank my loving wife. Not only has she supported my research and acted as a constant inspiration to me, but she has been unwavering in her willingness to help me overcome all obstacles during my graduate career. From staying by my side during a brief medical scare to leaving her job and moving with me to New York, she has gone above and beyond what I could have hoped for.

CHAPTER 1. Introduction and literature review

1.1 Transfer ribonucleic acid (tRNA): functions and modification

Protein synthesis is the culmination of a process known as the central dogma of molecular biology [1]. In this activity, the information stored within 2'-deoxyribonucleic acid (DNA) is transcribed into messenger ribonucleic acid (mRNA). The mRNA is then loaded onto a ribosome composed of ribosomal ribonucleic acid (rRNA) and protein. Once on the ribosome, triplet nucleotide sequences, or codons, on the mRNA are recognized by the anticodon residues of transfer ribonucleic acid (tRNA), which bring the correct amino acid to the ribosome for addition to the growing peptide chain. Since there are 64 possible triplet combinations of the four canonical RNA residues in the genetic code (61 that code for amino acids) and only 20 common amino acids, there is degeneracy in the code (Figure 1). In addition to this, there are often fewer tRNAs than codons. The main cellular role of tRNA is to bring the correct amino acid to the ribosome for protein synthesis through base pairing between the three anticodon residues in the tRNA and the codon residues of the mRNA. Therefore, to properly navigate the degenerate genetic code, tRNAs with many different anticodon sequences must conform to a common structure when bound to the ribosome and have the ability to specifically recognize multiple codons in certain situations.

The tRNA secondary structure is in the shape of a cloverleaf [2] consisting of the aminoacyl acceptor stem, a variable loop and three stem and loop domains: the dihydrouridine stem and loop (D-loop), the thymidine stem and loop (T-loop or T ψ C-loop) and the anticodon stem and loop (ASL) domain (Figure 2a). As shown in early crystal structures of yeast tRNA^{Phe} [3,4] and confirmed a few years later with yeast tRNA^{Asp} [5,6], the tRNA folds into an L-shaped tertiary structure in which the aminoacyl acceptor stem is at one end and the ASL is at the other (Figure 2b; [7]). Interestingly, tRNAs with unusual secondary structure characteristics such as the eukaryotic selenocysteine tRNA^{Sec} [8] show that the highly canonical L-shaped tertiary structure is not a necessity for tRNA function.

However, the high resolution structures show that the locations and rotational displacement of the aminoacyl acceptor stem and ASL are highly conserved even in this unusual structure [9]. It should also be noted that the decoding region, the ASL, is not stabilized or structured by any tertiary interactions from the other tRNA domains. Therefore, it must independently conform to the geometry necessary for decoding in the ribosomal A-site as well as carry the chemistry required for base pairing with multiple codons. Nature accomplishes this feat through chemical modification of the tRNA residues.

During maturation of a tRNA transcript, specific nucleoside residues are chemically modified via reactions catalyzed by modification enzymes [10]. The high propensity for tRNAs to be modified is inherent in the fact that two of the stem loops are named by the highly conserved modified residues contained within them, dihydrouridine in the D-loop and thymidine and pseudouridine in the T-loop. In fact, of the 109 currently known naturally occurring post-transcriptional RNA modifications, 92 are found in tRNA [11]. At least twelve of these, including the common ASL modifications *N*⁶-threonylcarbamoyl adenosine (t⁶A) and inosine (I), can be found in tRNA from all three phylogenetic domains [11-13]. While the diversity of tRNA modification chemistries highlights the probability that specific modifications evolved to perform specific functions based on the needs of individual species, the phylogenetic conservation of a subset of them suggests that tRNAs and their modifications may have even been important to the progenitor prior to the divergence of phylogenetic domains.

The cellular roles of many tRNA modifications have yet to be deciphered; however, their high importance can be inferred from the energetic cost and the amount of genetic information devoted to modifications as well as their abundant usage in tRNAs. In a “back of the napkin” calculation in 1995, Glenn Bjork estimated that tRNA genes make up ~0.25% of the *Escherichia coli* genome, while at least four times that amount, ~1%, is devoted to tRNA-modifying enzymes [12]. While the energy consumption required for generating small amounts of these modification enzymes is relatively low, one must consider that many of these enzymes require *S*-adenosylmethionine (SAM), for which the synthesis of just one

molecule requires 12 molecules of ATP [14-16]. The highly modified nature of tRNAs adds to the energy requirement. In fact, up to 25% of the tRNA residues are modified in some eukaryotes [13]. The large amount of modifications present in tRNAs and the energetic devotion required highlights their importance to all cells.

The tRNA anticodon domain contains a number of conserved sequence properties (Figure 3). In addition to being the most heavily and variously modified RNA domain, the ASL is always characterized by a five base-pair stem and seven nucleotide loop. Within the stem, there is very little sequence conservation; however, the nucleotides co-vary to allow for a highly stable stem consisting of A-form RNA with Watson-Crick base pairing. More pronounced sequence conservation occurs in the loop, with the exception of the anticodon residues, which must co-vary with cognate and synonymous codons. Within the loop, the most common sequence is 5'-C₃₂U₃₃N₃₄N₃₅N₃₆A₃₇A₃₈-3', which is found in 38.5% of all known tRNA sequences. In fact, U₃₃ is nearly universal, occurring in all cytoplasmic, plastid and viral tRNAs and in all but seven known mitochondrial tRNAs [13]. While position 37 is nearly always a purine (>99%), the great majority of the time (>70%), this comes in the form of an adenosine [13]. Finally, other than the anticodon, the least conserved of the loop residues are at positions 32 and 38 where C₃₂ (~68%) and A₃₈ (~69%) are most common [13]. Interestingly, this sequence conservation does not necessarily cause the loop to occupy a conserved conformation. Here, modifications can cause alterations in both conformation and structural dynamics in order to overcome the conformational limitations that sequence conservation cannot overcome.

1.2 Anticodon domain modifications

1.2.1 Position 34 modifications

Within the subset of modifications found in tRNAs, the largest number and greatest chemical diversity can be found within the ASL domain [11,13]. The most commonly

modified residues in the ASL occur at the first anticodon residue, position 34, and 3' adjacent to the anticodon, position 37 [11,13]. Position 34, known as the “wobble” position (see nucleoside numbering in Figures 3,5,6), is so called because of Francis Crick’s famous “Wobble Hypothesis” in 1966, which notes the unusual ability of uridine (U), guanosine (G) or inosine (I) at this position to “wobble” base pair with two or three different codons [17]. This ability to “wobble” explains how tRNAs with these position 34 residues can decode two or three codons differing in their third residue; thus, accounting for a certain amount of degeneracy within the genetic code.

The extensive study and the large diversity of modification chemistries located at position 34, most specifically in modified uridines, prompted the “Modified Wobble Hypothesis” in 1991 [18]. This hypothesis encompassed the evidence that while U, G and I can expand the decoding ability of the anticodon, modifications can modulate the expansion or restriction of wobble decoding to fine-tune these interactions [18]. In the case of many mitochondria [19,20] and plastids [21,22], an unmodified wobble position uridine is sufficient to expand the decoding ability of the isoacceptor to read all four codons in a box; however, cytosolic tRNAs with wobble position uridines are rarely able to efficiently decode any codons in the absence of modification. Indeed, 84% of the uridines found at the wobble position of cytosolic tRNAs are modified [23] to either expand [24-27] or restrict [28-31] the decoding ability of these uridines. Interestingly, in contrast to the differences in the Watson-Crick faces of the wobble nucleosides that prompted the original Wobble Hypothesis, the largest and most diverse of these uridine modifications occur at the 5-position, opposite the Watson-Crick face [11]. It is clear that for these 5-modified uridines to regulate wobble decoding, the structure and geometry of the nucleoside is just as important as the chemistry of the Watson-Crick face. In fact, a strong correlation has been found between the conformation of the ribose moiety and the tRNAs decoding ability. When a 5-position modification of uridine promotes either a C2'-*endo* or C3'-*endo* sugar pucker, there tends to be an expansion or restriction of the decoding capacity, respectively [18,32,33]. However, it should also be noted that the 5-modified uridines that restrict wobble decoding also tend to have a 2-

thiolation, which does change the chemistry of the Watson-Crick face, but also further stabilizes the C3'-*endo* sugar conformation [34-37].

Position 34 adenosines (A) are nearly universally modified to the guanosine analog inosine. In fact, only four instances [13] have been found where a wobble position adenosine is not modified to inosine (*Mycoplasma capricolum* [38,39] and *Mycoplasma mycoides* [40,41] tRNA^{Thr}_{AGU} and the mitochondrial tRNA^{Arg}_{ACG} of *Saccharomyces cerevisiae* [42] and *Ascaris suum* [43]). In comparison to bacteria where only tRNA^{Arg}_{ICG} contains inosine, in eukaryotes all fourfold degenerate codon boxes are decoded by at least one isoacceptor that contains I₃₄. As mentioned above, inosine at position 34 (I₃₄) in the ASL allows recognition of codons ending in U, C or A. Although the positioning of the I₃₄•A₃ anticodon•codon base pair suggested in the original wobble hypothesis was in the traditional Watson-Crick geometry [17], this does not account for the increased size of the two purine residues within the ribosomal A-site. It was theorized that the geometry of this purine•purine base pair required that the inosine must adopt a *syn N*-glycosidic bond conformation, exposing the Hoogsteen face for base pairing with the Watson-Crick face of A₃₈ [44]. A crystal structure of the I₃₄ modified *E. coli* ASL^{Arg}_{ICG} in the ribosomal A-site revealed that the I₃₄•A₃ base pair is indeed in the Watson-Crick geometry, and this is accomplished by a compression of the ribose and phosphate moieties between C1' and P, most drastically in the β (P-O5'-C5'-C4') torsion angle, which changes from about ±180° to -37.8° [45].

1.2.2 Position 37 Modifications

Another commonly modified nucleoside in the ASL occurs with the purine residue at position 37. This purine residue is so highly conserved and highly modified that >99% of the known tRNA sequences contain a purine at position 37 and >70% are modified [13,46]. Modifications at this position have a correlation to the identity of the residue at position 36 [47,48]. A notable example of this occurs where tRNAs with U₃₆, with very few exceptions, also contain N⁶-threonylcarbamoyl adenosine (t⁶A) or its derivatives at position 37 [13]. These hypermodified t⁶A₃₇ derivatives have been shown, through structural determination, to

form a base stacking interaction over the A₁•U₃₆ codon•anticodon base pair, thereby stabilizing the low enthalpy of this base pair [47,49]. In addition to stabilization, structural studies of the human tRNA^{Lys3}_{UUU} ASL indicate a role for t⁶A₃₇ and ms²t⁶A₃₇ in negating intraloop hydrogen bonding in the pyrimidine-rich loop, resulting in an opening of the tri-nucleotide loop into a canonical 7-membered loop [50,51]. This loop rearrangement ability appears to be a pre-requisite for the formation of a U-turn motif and further stabilize this conformation.

For ASLs that have G₃₆, 78% of the position 37 residues are methylated purines [13]. In most cases (83%) this methylated purine is 1-methylguanosine (m¹G₃₇); however, in some cases (17%) there is either a 2-methyladenosine (m²A₃₇) or 6-methyladenosine (m⁶A₃₇) [13]. The increased stability of C₁•G₃₆ codon•anticodon base pairs reduces the need for a stabilizing stacking interaction from the position 37 nucleoside. Instead, the small hydrophobic modifications prevent translational frameshifting [52,53] and significantly increase affinity of the cognate codon•anticodon interaction [54]. The positioning of the methylations on the Watson-Crick face of these purines also underscores the possibility that these modifications may effect frameshifting or misreading by preventing either base pairing of these residues to the nucleoside 5' adjacent to the codon [53] or to the invariant U₃₃ 5' adjacent to the anticodon, disrupting the possibility of forming a tri-nucleotide loop structure.

1.2.3 Position 32 Modifications

Finally, although modifications at position 32 are not usually discussed with commonly modified anticodon domain modifications, ~32% of known tRNA sequences contain a modification at this position [13]. This nucleoside, at the base of the stem is nearly always a pyrimidine (>99%) [13] and is located directly across the loop from the commonly unmodified and less conserved residue at position 38 (Figure 3). The geometry of the non-canonical interaction between position 32 and position 38 residues (including the modified residues pseudouridine and 2'-O-methylcytidine at position 32) has been thoroughly studied and shown to significantly affect the ability of the tRNA to discriminate between codons

[55]. In all of these structures, the geometry of this base pair is stabilized by stacking interactions with the stem residues, requiring a stabilized A-form-like C3'-*endo* sugar pucker [56-61]. Interestingly, 83% of nucleoside modifications that occur at position 32 are either 2-thiocytidine or 2'-*O*-methylated pyrimidines [13], both of which stabilize the C3'-*endo* conformation. Specifically, the increased size of the thioketone and the large, hydrophobic nature of the 2'-*O*-methyl group each cause steric clashes in the C2'-*endo* conformation resulting in a significant preference for the C3'-*endo* pucker [33,62-64]. Additionally, the 2-thiolated pyrimidines experience greater stacking interactions caused by the greater polarizability of sulfur in comparison to oxygen [37]. Therefore the highly modified nature of this residue may have important implications for the tRNAs ability to decode.

1.3 Modulation of anticodon stem and loop structure, stability and function

We have now established that modification of tRNA is done at great cost in terms of genetic material, precursors, modifications enzymess and cellular energy, and that modifications are prominent aspects of the anticodon domain. Functionally, ASL modifications are important for accuracy and efficiency of protein synthesis. These modifications have been shown to be important for many different features of translation such as thermal stability of the ASL [28,65-70], decoding specificity [70-74], ribosomal codon binding affinity [28,65,75-77], proper translocation [77] and reading frame maintenance [78-81]. Additionally, pre-structuring of the ASL toward a canonical U-turn structure in solution for proper recognition in the ribosomal A-site is a common function of anticodon domain modifications [70,78,82,83]. The formation of a U-turn-like structure in solution is beneficial to the cell because it reduces the energy barrier of binding to synonymous mRNA codons in the ribosomal A-site.

The U-turn motif has many characteristics that make it ideal for proper function in the decoding center of the ribosomal A-site (Figure 4). Structurally, there is an abrupt change in direction of the RNA backbone at the universal U₃₃ residue and a well-ordered base stacking

network along the 3' side of the loop that results in the three anticodon residues being exposed in the proper geometry for codon binding [45,49]. Also, a non-Watson-Crick base pair is typically formed between the first two residues of the loop (N₃₂•N₃₈), resulting in a pseudo-5nt loop. Finally, the highly stacked nature of the 3' side of the loop results in a highly stabilized stem loop structure. To achieve this ideal structure in all tRNAs, a high amount of sequence conservation has evolved in the non-anticodon residues of the anticodon loop (Figure 3). However, the need for differences in the sequence of the three nucleotide anticodon can significantly alter the structure of the loop. Indeed it has been shown that the highly dynamic nature of the pyrimidine rich anticodon of unmodified ASL^{Lys}_{UUU} causes the formation of stable cross-loop base pairs, resulting in a very rigid tri-nucleotide loop conformation [84,85].

Since differences in anticodon sequence can cause disruption of the U-turn conformation, chemical modifications to the anticodon loop residues can restore a more canonical structure. In the case of ASL^{Lys}_{UUU}, modifications at positions 34 and 37 not only disrupt the cross-loop interactions that cause the tri-nucleotide loop conformation, but also contribute to a prestructuring of the ASL into a canonical U-turn motif [51,84,85]. A fully canonical U-turn conformation is not a necessity, however, for binding to the ribosomal A-site. As seen with ASL^{Val}_{UAC} [24,86] and ASL^{Lys}_{UUU} [51], small deviations are seen in solution structures of the modified ASL to that of the crystal structures on the ribosome. The energy barrier associated with the conformational transition between the solution structure and the structure on the ribosome is a determining factor for fine tuning of induced-fit remodeling and, therefore, of translational speed and accuracy. The fine tuning capability associated with the strength and geometry of the N₃₂•N₃₈ cross-loop interaction [55,87] indicates a possible role for chemical modifications at positions 32 and 37 to have either subtle or drastic effects on the energy barrier associated with this structural transition. Additionally, as noted above, modifications at position 34 can alter the sugar pucker at this position, significantly affecting the structural characteristics of the anticodon loop [18,32,33]. The effects of these modifications on loop structure and flexibility must be more pronounced in isoacceptors that require similar

conformational abilities for recognition by a single aminoacyl-tRNA synthetase, but have multiple anticodon nucleotide sequences such as the case of six-fold degenerate codons.

In addition to their structural function, ASL modifications have recently been shown to be dynamic and can regulate gene expression. It has been suggested that tRNA modification levels may be used as a regulatory device in response to such factors as antibiotics, iron levels and aerobic vs anaerobic growth [88]. Indeed, recent evidence shows alteration in the state of overall tRNA modification during stress conditions in *Saccharomyces cerevisiae* [89]. Also, the efficient synthesis of 5-methoxycarbonylmethyl-2-thiouridine (mcm⁵s²U) in *Saccharomyces pombe* is required for proper transition through the cell cycle in a modification dependent manner [90]. While there is substantial sequence data for tRNAs and their modifications [13], during purification and determination of modified residues present in many isoacceptors, wild type cells were typically grown under only one environmental circumstance (ie. in rich media at optimal growth temperature) to obtain a suitable amount of material; therefore it remains unclear as to whether modifications respond to specific environmental or stress conditions as a common regulatory device.

1.4 Six-fold degenerate decoding of arginine in *Escherichia coli*

Arginine shares the distinction (with leucine and serine) of being one of only three amino acids that is decoded by six codons (Figure 1). In *Escherichia coli*, these six codons are decoded by five tRNA isoacceptors (Figure 5; [13,91,92]). Interestingly, the usage of these six codons in *E. coli* varies wildly from > 2% of all codons for CGU and CGC to < 0.6% for CGA, CGG, AGA and AGG (Table 1; [93-95]). Three of the four less common codons (CGG, AGA and AGG) are decoded by individual isoacceptors, whereas the two most common codons (CGU and CGC) are decoded by the same isoacceptors (tRNA^{Arg1,2}_{ICG}) as the rare CGA codon. This marks a rare instance in which a single tRNA isoacceptors is solely responsible for recognition of both very common and very rare codons.

While the primary sequences of their anticodon domains are quite different, commonalities can be found in arginyl-isoacceptors. In addition to the less notable invariant U₃₃, highly conserved A₃₈ and middle anticodon nucleotide C₃₅, the rare 2-thiocytidine modification is present at position 32 in four of the five isoacceptors. This modification is only found in tRNA^{Arg1,3,4,5} and tRNA^{Ser2}_{GCU} in select bacteria and archaea [13]. Extensive studies have been performed to elucidate the function of 2-thiolated uridines at the wobble position [28,49,51,71,84]; however, relatively little is known about s²C₃₂. Chemical similarities between the two pyrimidines suggest that a 2-thiolation of cytidine would elicit similar structural properties as seen in s²U. In comparison to oxygen, the sulfur atom has a lower electronegativity, resulting in greater stacking interactions for s²U₃₄ [37]. In addition, as mentioned above, the increased size of sulfur over oxygen in s²U₃₄ causes steric effects forcing the ribose to adopt a C3'-*endo* pucker conformation and enhancing the *anti*-conformation of the *N*-glycosidic (χ) dihedral angle [34-37]. Empirical evidence of this was shown in the altered accessibility of the tRNA^{Arg1,2}_{ICG} anticodon loop to nuclease S1 upon chemical conversion of s²C₃₂ to C₃₂ [96]. Functionally, s²C₃₂ promotes reading frame maintenance [96] and reduces the rate of tRNA selection into the ribosomal A-site [97]. Interestingly, however, a *Salmonella enterica* mutant without s²C₃₂ exhibits wild type growth under optimal growth conditions, thus it has been proposed that the s²C₃₂ modification could be important for improving accuracy by reducing the speed of translation [97], a function that may only be necessary during suboptimal growth conditions.

Three of the six arginine codons (CGU, CGC and CGA) are decoded by the tRNA^{Arg1}_{ICG} and tRNA^{Arg2}_{ICG} isoacceptors. In *E. coli*, these two isoacceptors are expressed from a common gene and, thus, their primary sequences are nearly identical. There are only two differences between these two tRNAs: (1) tRNA^{Arg2}_{ICG} contains an additional adenosine nucleotide at position 20 (A₂₀) in the dihydrouridine loop and (2) tRNA^{Arg1}_{ICG} contains the rare modification 2-thiocytidine at position 32 (s²C₃₂), whereas tRNA^{Arg2}_{ICG} has an unmodified C₃₂ (Figure 5; [13]). Interestingly, both A₂₀ and s²C₃₂ are present in tRNA^{Arg3,4,5}. In addition to the s²C₃₂ found only in tRNA^{Arg1}_{ICG}, both tRNA^{Arg1}_{ICG} and tRNA^{Arg2}_{ICG} contain

modifications at position 34 (inosine, I_{34}) and position 37 (2-methyladenosine, m^2A_{37}). Wobble position inosines (I_{34}) are a very common adenosine modification. In fact, as mentioned above there are only four known instances where this position contains an unmodified adenosine [13,38-43]. Inosine has the well-known function of enabling tRNAs to decode codons ending in U, C or A, whereas an unmodified adenosine and guanosine recognize only U, and U or C, respectively. In a majority of cases, I_{34} is accompanied by a modification at position 32 or a modification at position 37 (~67% and ~82%, respectively), and ~56% in both positions [13]. While, the function of I_{34} can be assumed to be expansion of the decoding capability to three codons, the roles of the additional modifications at positions 32 and 37 remain unclear. More specifically, the roles of the rare tRNA^{Arg1,2}_{ICG} modifications s^2C_{32} and m^2A_{37} (present in only five and 13 known tRNA isoacceptors, respectively [13]), in the context of I_{34} in tRNA structure and function are not understood.

Another interesting isoacceptor is *E. coli* tRNA^{Arg4}_{UCU}. Of particular interest is that in this tRNA the 5-methylaminomethyluridine at position 34 (mnm^5U_{34}) causes this isoacceptor to recognize only one of the rare codons AGA, but not AGG [30], whereas, in *E. coli* tRNA^{Lys}_{UUU}, it confers the ability to read both AAA and AAG codons [28]. Ribosome binding studies directed toward understanding each chemical modification moiety using the anticodon domain of tRNA^{Lys}_{UUU} confirm that the mnm^5 modification alone is sufficient to allow recognition of both codons [28,75]. Indeed, a crystal structure of this ASL bound to AAG in the A-site of the 30S ribosomal subunit clearly shows that the recognition is allowed by the specific positioning of the mnm^5U_{34} residue which positions it in just the right geometry for a bifurcated hydrogen bond between the O2 of mnm^5U_{34} and the N1H and N2H of the codon G₃ [49]. The only differences in the loop sequence of *E. coli* tRNA^{Lys}_{UUU} and tRNA^{Arg4}_{UCU} is the identity of the second anticodon nucleoside and the s^2C_{32} modification in tRNA^{Arg4}_{UCU} (Figure 6). If both anticodon loops are so similar, how is it that they have different decoding functions when it comes to wobble codon discrimination?

Three projects are presented herein in which we ask the questions: (1) What roles, if any, do anticodon domain modifications play in the ability of tRNA^{Arg1,2}_{ICG} to distinguish between

the common CGU and CGC codons and the rare CGA codon? (2) Are modifications important for modulating flexibility of the loop and, thus, altering the energy barrier between different necessary conformations? (3) How do s²C₃₂ and/or C₃₅ cause a restricted decoding functionality for tRNA^{Arg4}_{UCU} when the very similar anticodon loop of tRNA^{Lys}_{UUU} promotes wobble decoding? To study these tRNAs in a modification dependent manner, a smaller model system consisting of the ASL was utilized. As mentioned previously, this portion of the tRNA does not make any contact with any other tRNA domains (Figure 2b). Also, many NMR solution and X-ray crystal structures show a very high degree of conformational similarity between ASLs and their corresponding tRNAs [3,24,51,66,86]. This information, coupled with corroborating ribosome binding data, indicates that the ASL is a sufficient model system to test the effects of anticodon domain modifications. With this system, it is possible to select and site specifically incorporate modified residues into the heptadecamer hairpin using standard RNA synthesis chemistry. Using synthesized ASLs in different states of modification, comprehensive biochemical analyses such as functional binding assays, thermodynamic characterization and structure determination have given key insights into answering the questions posed above. Additionally, computational approaches have been utilized where empirical experiments were not feasible.

2.1 Statement of project contribution

The comprehensive detail with which this project was composed hinged on coordinated efforts in three main areas. For this project, I, along with Dr Paul F. Agris, acted in a supervisory role for the entire effort. The first component, NMR, was mainly performed by Dr. Yann Bilbille. My role in this aspect was limited to interpretation of the structural data as well as relating this data to biophysical and functional characteristics of the RNA. I was responsible for biophysical and functional characterization using UV-monitored thermal denaturation and circular dichroism spectroscopies and functional binding assays. These assays were also optimized to account for non-specific binding events and calculate picomoles bound. I also mentored an undergraduate, Jia Kim, to assist with the analysis of the thermal denaturation data as well as to perform native polyacrylamide gel electrophoresis.

2.2 Abstract

Three of six arginine codons are read by two tRNA^{Arg} isoacceptors in *Escherichia coli*. The anticodon stem and loop (ASL^{Arg1,2}) of these isoacceptors differ only in that the position 32 cytidine of tRNA^{Arg1} is posttranscriptionally modified to 2-thiocytidine (s²C₃₂). The tRNA^{Arg1,2} are also modified at positions 34 (inosine, I₃₄) and 37 (2-methyladenosine, m²A₃₇). To investigate the roles of modifications in the structure and function, six ASL^{Arg1,2} constructs differing in their array of modifications were analyzed by spectroscopy and codon binding assays. Thermal denaturation and circular dichroism spectroscopy indicated that modifications contribute thermodynamic and base stacking properties, resulting in more order but less stability. NMR-derived structures of the ASL^{Arg1,2} showed that the solution structures of the ASLs were nearly identical. Surprisingly, none possessed the U-turn conformation required for effective codon binding on the ribosome. Yet, all ASL^{Arg1,2} constructs efficiently bound the cognate CGU codon. Three ASLs with I₃₄ were able to decode CGC, whereas only the singly modified ASL^{Arg1,2}_{ICG} with I₃₄ was able to decode CGA. The dissociation constants for all codon bindings were physiologically relevant (0.4 – 1.4 μM). However, with the introduction of s²C₃₂ or m²A₃₇ to ASL^{Arg1,2}_{ICG} the maximum amount of ASL bound to CGU and CGC was significantly reduced. These results suggest that by allowing loop flexibility the modifications modulate the conformation of the ASL^{Arg1,2} which takes one structure free in solution, and two others when bound to the cognate arginyl-tRNA synthetase, or to codons on the ribosome where modifications reduce or restrict binding to specific codons.

2.3 Introduction

Transfer RNA (tRNA) molecules translate the genetic code by recognizing triplet codons on messenger RNA (mRNA) during protein synthesis. The ribosome-mediated interaction of the mRNA codons with the anticodon of the tRNA results in discrimination of synonymous versus non-synonymous codons. No less than 93 different naturally-occurring

posttranscriptional modifications are found in tRNAs, each with unique hydrophobic or hydrophilic properties [1-3]. These modifications play an important role in the accuracy and efficiency of protein synthesis. Modifications occurring in the anticodon stem and loop (ASL) domain of tRNAs are the most studied and the best understood. The majority of modifications and the most chemically complex occur at position 34 or at position 37, immediately 3' adjacent to the anticodon triplet. These anticodon domain modifications alter conformation and thermal stability [4-10], enhance decoding specificity [10-14], enhance ribosomal binding [4,6,15-17], promote proper translocation [17] and maintain the translational reading frame [18-21]. Anticodon domain modifications have been shown to be essential for pre-structuring the ASL toward a canonical U-turn structure in solution for proper recognition in the ribosomal A-site [2,10,18,22].

Escherichia coli (*E. coli*) has five tRNA^{Arg} isoacceptors, four of which have the modification 2-thiocytidine at position 32, s²C₃₂ (Figure 1a [23]). The only other *E. coli* tRNA having s²C₃₂ is tRNA^{Ser2}_{GCU} [23]. As such, the s²C₃₂ modification is highly interesting. It is one of the rarest of modifications [1], but found within a very common anticodon domain consensus sequence element, C₃₂U₃₃NNNA₃₇A₃₈. A C₃₂ or s²C₃₂ appears in 56% of all *E. coli* sequences along with A₃₈ that appears in 69% of the sequences. The only other known nucleoside thiolations are s²U₃₄ and its derivatives, s⁴U₈, and four different 2-methylthio-derivatives of adenosine [1]. In contrast to what is known about these modifications, the contribution of s²C₃₂ to the structure and function of the tRNA^{Arg} isoacceptors and their abilities to decode the six arginine codons has not been explored in detail [24,25].

The unmodified, primary nucleotide sequence of the ASL of the tRNA^{Arg1} isoacceptor and that of tRNA^{Arg2} are identical [26,27]. Therefore, to avoid confusion they are denoted as ASL^{Arg1,2} for the purposes of this study (Fig. 1a). The two isoacceptors are derived from a common gene and only differ at two positions in the entire tRNA sequence. tRNA^{Arg1} has the rare modification s²C₃₂ whereas tRNA^{Arg2} has an unmodified C₃₂ (Fig. 1a). In addition, tRNA^{Arg1} lacks A₂₀ of the dihydrouridine loop. A₂₀ is invariant in the other four isoacceptors

[23,26,27] and has been shown to be an important identity determinant for aminoacylation [28]. Indeed, mutant tRNA^{Arg2} transcripts in which the A₂₀ is either substituted or deleted result in a 370-fold decrease in aminoacylation activity suggesting that tRNA^{Arg1}_{ICG} is aminoacylated with a lower efficiency than tRNA^{Arg2} [29]. The anticodon domains of the two isoacceptors also have an inosine modification at the “wobble” position 34 (I₃₄) and a 2-methyladenosine at position 37 (m²A₃₇), 3' adjacent to the anticodon (Fig. 1b,c). Thus, the tRNA^{Arg1,2}_{ICG} isoacceptors have the anticodon of ICG (Fig. 1a). In agreement with the “wobble” hypothesis [30], the guanosine analog inosine, derived from adenosine and located at position 34 allows tRNA^{Arg1,2}_{ICG} to decode three of the four-fold degenerate codons (CGU, CGC and CGA). In comparison, tRNA^{Arg5}_{CCG} with a cytidine at position 34 reads only the fourth codon CGG.

The functions of s²C₃₂ and m²A₃₇ are not fully understood. Both exclusively occur in anticodon loops containing a pyrimidine at position 35 [23,31]. The s²C₃₂ is found in four of the five *E. coli* tRNA^{Arg} isoacceptor species, tRNA^{Arg1,3,4,5}, and tRNA^{Ser2}_{GCU}. All s²C₃₂ containing tRNA isoacceptors in *E. coli* have common sequence characteristics. In addition to the s²C₃₂, they all have a modified purine at position 37 (Fig. 1 [23,31]). Additionally, they all contain an A₃₈ at the 3'-terminus of the anticodon loop [23,31], and thus a mismatch base pair between A₃₈ and C₃₂/s²C₃₂ can be formed (Fig. 1). The classic bifurcated hydrogen bond observed between O2 (C₃₂) and N6 (A₃₈) in tRNA [32] has been shown to be stable over the nanosecond time scales of molecular dynamics simulations [33,34]. All contain a conserved C₃₅ at the second position of the anticodon [31] and the invariant U₃₃ responsible for the ubiquitous U-turn in tRNA anticodons. C₃₅ has been shown to be an important identity element for aminoacylation [27,28].

Although a mutant without s²C₃₂ exhibited wild-type growth, the A-site selection rate for the tRNA^{Arg3} in response to the AGG codon was dependent on this thiolated nucleoside in *Salmonella enteric* [35]. The sulfur atom at position 2 of pyrimidines is known to stabilize stacking interactions by its greater polarizability than oxygen and to promote the C3'-endo, anti-conformation of the nucleoside in RNA [36]. Since the bases of nucleosides 31, 32 and

33 should be stacked in the classic U-turn conformation, one wonders how an increase in stacking induced by the 2-thiocytidine may influence the base pairing of C₃₂ with A₃₈. The structure of the *E. coli* tRNA^{Arg1,2}_{ICG-s²C₃₂} free in solution may be influenced by the s²C₃₂ modification because a change from C₃₂ to s²C₃₂ results in an altered accessibility of the anticodon loop to nuclease S1 to a pattern more indicative of an initiator than an elongator tRNA [37]. The s²C₃₂ modified nucleoside of the *E. coli* tRNA^{Arg1,2}_{ICG-s²C₃₂,m²A₃₇} maintains the translation reading frame, preventing formation of an incorrect protein, the product of a -1 frameshift, during *in vitro* synthesis of the T4 phage coat protein [37]. In this case, the s²C₃₂ modification promotes the correct reading of the mRNA. In fact, chemical alteration of the s²C₃₂ to C₃₂ results in a decrease in the ability of the tRNA to maintain the reading frame [37]. However, in single point binding experiments using the fully modified tRNA^{Arg1,2}_{ICG-s²C₃₂,m²A₃₇}, there does not seem to be a significant change in the ribosome binding characteristics in comparison to a tRNA without the s²C₃₂ modification [38]. In fact, it has been suggested that the s²C₃₂ modification could be important to improve accuracy by reducing the speed of translation [35].

We have investigated the importance of all three modifications in tRNA^{Arg1,2}_{ICG} by biochemical, thermodynamic and structural techniques using six differentially modified, heptadecamer ASLs corresponding to the unmodified ASL^{Arg1,2}_{ACG}, singly modified ASL^{Arg1,2}_{ACG-s²C₃₂}, ASL^{Arg1,2}_{ACG-m²A₃₇} and ASL^{Arg1,2}_{ICG}, and the doubly modified ASL^{Arg1,2}_{ICG-s²C₃₂} and ASL^{Arg1,2}_{ICG-m²A₃₇} (Fig. 1b). Structures of four of the ASLs, ASL^{Arg1,2}_{ACG}, ASL^{Arg1,2}_{ACG-s²C₃₂}, ASL^{Arg1,2}_{ICG} and ASL^{Arg1,2}_{ICG-s²C₃₂}, have been solved by NMR spectroscopy and restrained molecular dynamics. Combinations of anticodon domain modifications modulate the structural flexibility of the anticodon loop and responsiveness to the three degenerate codons. The ASLs lack the classical U-turn and present a singular conformation in solution that is incongruous with the canonical anticodon structure thought to be required for ribosome-mediated codon binding. The results of this study indicate a possible regulatory role for these modifications in decoding of the genome. By modulating the structural dynamics of the loop nucleosides, the modifications alter the codon reading

capacity of the tRNA to a preference for the more commonly used CGU and CGC codons over the rarer CGA codon.

2.4 Results

2.4.1 Modifications remodel thermodynamic properties and conformational dynamics

Constructs of the anticodon stem and loop domain of *E. coli* tRNA^{Arg1,2} (ASL^{Arg1,2}) were chemically synthesized with site-selected introduction of naturally-occurring, post-transcriptional modifications. Standard protection and phosphoramidite chemistries, as well as 5'-silyl-2'-acetoxyethyl orthoester ('ACE') chemistries, were employed for introduction of the modified nucleosides [39]. Six different ASL^{Arg1,2} constructs were synthesized, differing in the state of modification (Fig. 1c). Thermodynamic properties and base stacking contributions of the modifications were assessed using UV-monitored thermal denaturation and renaturation, and circular dichroism, CD (Fig. 2). In general, the addition of modifications reduced thermal stability while modestly adding to structural order through base stacking (Table 1). When compared to the unmodified ASL, neither the introduction of inosine at position 34 (I₃₄) nor 2-methyladenosine at position 37 (m²A₃₇) alone changed the melt temperature, the temperature at which half of the ASL molecules were fully denatured, T_m (Fig. 2a,b; Table 1). Introduction of I₃₄ resulted in a modest increase in the Gibbs free energy, ΔG₃₇. In contrast, a single 2-thiocytidine at position 32 (s²C₃₂) of the ASL caused the most significant reduction in T_m by 4.8 °C and a correspondingly large increase in ΔG₃₇ (Fig. 2a; Table 1). The addition of s²C₃₂ to the inosine-modified ASL^{Arg1,2}_{ICG} resulted in a less drastic, but significant, destabilization compared to that of s²C₃₂ alone (ΔT_m = -3.7 °C). Though the introduction of m²A₃₇ did not alter the thermodynamic properties of an otherwise unmodified ASL^{Arg1,2}_{ACG}, m²A₃₇ produced a modest destabilization of the ASL^{Arg1,2}_{ICG} relative to the thermodynamic properties of the unmodified ASL^{Arg1,2}_{ACG} and ASL^{Arg1,2}_{ICG}.

Differences in hyperchromicity monitored during thermal denaturations, and differences in ellipticity of circular dichroism (CD) spectra are indicative of changes in base stacking that occur with the introduction of a modified nucleoside [18,22]. However, hyperchromicity measurements of an ASL composed of a five base paired stem and a seven nucleoside loop are monitored at ~260 nm and influenced mostly by the ten nucleosides of the RNA's base paired stem. In comparison, ellipticity measurements, conducted over a large range of wavelengths and in the native state of the RNA when observed at ambient temperatures, reflect the nucleosides of the seven membered loop as well as the ten nucleosides of the stem. Thus, the two measures of base stacking do not always agree [4]. The CD spectra of the ASLs exhibited the positive ellipticity ($\Delta\epsilon$) that occurs between 250-290 nm ($\lambda_{\max} \approx 268$ nm) and is indicative of A-form RNA (Fig. 2b). The two constructs containing m^2A_{37} also exhibited the minor positive ellipticity (290-320 nm) characteristic of this modification.[40,41]. The signature ellipticity of m^2A_{37} was more pronounced in the doubly modified ASL^{Arg1,2}_{ICG}- m^2A_{37} . The ASLs containing s^2C_{32} did not exhibit the positive ellipticity characteristic of the thio group of s^2U at 310 nm (Fig. 2 [42]). This ellipticity was not observed in spectra of the mononucleoside s^2C under the same conditions employed for observation of the ASLs (data not shown). Thus, lack of the 2-thio ellipticity at 310 nm for s^2C appears to be a difference in the CD properties of the two pyrimidine ribonucleosides, rather than a conformational difference caused by the modification.

Introduction of the individual nucleosides I_{34} and m^2A_{37} into the ASL^{Arg1,2}_{ACG} altered the base stacking as evidenced by a reduction in hyperchromicity during thermal denaturations (Table 1). The addition of s^2C_{32} to the ASL^{Arg1,2}_{ACG} did not appreciably change the hyperchromicity (Fig. 2a; Table 1). The hyperchromicity of both doubly modified constructs ASL^{Arg1,2}_{ICG}- s^2C_{32} and ASL^{Arg1,2}_{ICG}- m^2A_{37} was reduced by approximately 4% compared to that of the unmodified ASL^{Arg1,2}_{ACG} and could be attributed to the introduction of I_{34} on the 3'-side of the anticodon loop (Table 1). However, the CD ellipticity of the ASL^{Arg1,2}_{ICG}- m^2A_{37} increased relative to that of the unmodified ASL^{Arg1,2}_{ACG} indicating that the m^2A_{37} modification ordered the 3'-side of the loop (Fig. 2b(ii)). The increase in order on the 3'-side

of the anticodon is indicative of an enhanced base stacking by m^2A_{37} and a concomitant reduction in the normally large amount of conformational space in the loop. This increase in ellipticity could also be attributed to the altered chemical properties inherent with the methylated residue; however, studies have shown that the methyl group of a 2'-deoxy-5-methylcytidine does not impart any intrinsic CD character [43]. Our observations of changes in thermal stability, hyperchromicity and CD ellipticity for the variously modified $ASL^{Arg1,2}$ are similar to effects reported for modifications that occur on the 5'- vs. 3'-sides of anticodon loops [44]. Modifications of nucleosides on the 5'-side of the anticodon loop such as those at wobble position 34 tend to disorder and destabilize the structure. Modifications on the 3'-side of the loop at positions 37, 38 and 39 tend to enhance the 5'-3' base stacking found in tRNAs and ASLs, though these very same modifications negate intra-loop hydrogen bonding [5,44,45]. In summary, the introduction of anticodon domain modifications on the 5'-side of the loop, s^2C_{32} and I_{34} reduced the thermal stability of the $ASL^{Arg1,2}_{ACG}$, and modification on the 3'-side of the loop, m^2A_{37} , increased order through base stacking. Thus, the expected result from modification would be an anticodon domain with a canonical U-turn and the Watson-Crick face of the anticodon nucleosides exposed for codon binding.

2.4.2 Determination of $ASL^{Arg1,2}$ structures

The results of the thermal stability and base stacking studies suggested that the modified nucleoside contributions to the anticodon loop structure and conformational dynamics of $ASL^{Arg1,2}$ were qualitatively similar to that of other tRNAs. In order to determine if the modifications of $ASL^{Arg1,2}$ were driving the anticodon domain structure to that of the canonical conformation, four of the six differentially modified ASLs were studied by NMR and full, high resolution structures were calculated for $ASL^{Arg1,2}_{ACG}$, $ASL^{Arg1,2}_{ACG-s^2C_{32}}$, $ASL^{Arg1,2}_{ICG}$ and $ASL^{Arg1,2}_{ICG-s^2C_{32}}$. A considerable number of spectra were collected for $ASL^{Arg1,2}_{ICG-m^2A_{37}}$, but insufficient material was available for a full structure determination. All six differently modified $ASL^{Arg1,2}_{ACG}$ constructs were subjected to non-denaturing polyacrylamide gel electrophoresis, PAGE (Supplemental Information, Fig. S1). The results demonstrated that the ASLs were monomolecular species of potentially single conformation

at the concentrations tested. Surprisingly, there were no noticeable differences in the rate of migration due to the presence or identity of the modifications. All six ASLs were found to migrate within $\pm 1\%$ of the mobility of unmodified ASL^{Arg1,2}_{ACG}. The ASL^{Arg1,2} constructs migrated faster than the standard ASL, the unmodified yeast ASL^{Phe}, even though their molecular weights were all ~ 100 Da larger, perhaps suggesting a more compact structure in solution than a typical ASL with a U-turn. The results of pulsed field-gradient spin-echo NMR diffusion experiments also indicated that the ASLs were monomers in solution even at the higher concentrations required for determination of their structures by NMR (Supplemental Information, Table S1). Here we have focused our analysis on the structures of ASL^{Arg1,2}_{ICG} and ASL^{Arg1,2}_{ICG-s²C₃₂} because of the interest in understanding the effect of the rare modification s²C₃₂ on structure-function relationships.

NMR resonances assignments. Exchangeable ¹H NMR resonances were identified and assigned as accomplished previously for unlabeled, unmodified and modified ASLs [5,9,45-47]. The 1D spectrum recorded in water exhibited three sharp resonances in the imino region which were assigned to the imino resonances of the three guanines of the stem, G₄₁, G₃₁ and G₃₀, all involved in canonical G•C base pairing. Two other resonances, broader than the previous signals, were assigned to G₄₃H1 and U₂₈H3. A very broad exchangeable resonance was observed near 11 ppm, but was not assigned. No exchangeable proton resonances were observed near 15.5 ppm, characteristic of a protonated cytosine. Non-exchangeable resonances were assigned using well established techniques [48]. The sequential pathway of nuclear Overhauser enhancement, NOE, from the aromatic protons to the H1' of the 3' nucleoside could be followed from C₂₇ to C₃₅ and again from G₃₆ to G₄₃ with a break appearing between C₃₅ and G₃₆ (Fig. 3a). Though there was a break in the conventional NOE walk of A-form RNA, the G₃₆H8 had a very weak NOE with C₃₅H2'. This is indicative of C₃₅ not being stacked with G₃₆. The C₃₅/G₃₆ stack would be observed in the classical U-turn, and thus the canonical U-turn would not be expected to be present. The chemical shifts of H5, H6 and H8 are affected by the 5'-neighboring base when in an A-form helix.^[49] The C₃₅H5 chemical shift was not in agreement with a pyrimidine experiencing a 5'-purine ring

current [49], and thus was not supportive of the stacking of C₃₅ with A₃₄/I₃₄ that would be observed in a classical A-RNA or a U-turn.

Over 100 inter-nucleotide, sequential and non-sequential NOEs were observed for each of the ASL^{Arg1,2}_{ICG}, approximately half of these were for the anticodon loop and the adjacent nucleosides from 31 to 39 (Table 2; Fig. 4). On the 5' side of the loop, the s²C₃₂/C₃₂ was stacked with G₃₁ and U₃₃, as shown by the inter-aromatic NOEs between the G₃₁ and the unmodified or modified C₃₂ bases, and the latter with U₃₃ (G₃₁H8 - s²C₃₂/C₃₂H5 and G₃₁H8 - s²C₃₂/C₃₂H6; s²C₃₂/C₃₂H6 - U₃₃H6 and s²C₃₂/C₃₂H6 - U₃₃H5). The s²C₃₂ H1' downfield chemical shift (~6.1 ppm) was characteristic of the 2-thio-modification, as exemplified by that of s²U [50]. The I₃₄H2 was assigned by its C2 specific chemical shift, upfield from the main C2 resonances. Even in the 400 ms NOESY spectrum, the I₃₄H2 resonance did not exhibit an NOE with another aromatic or sugar proton resonance. Nevertheless, a weak NOE was observed between the U₃₃H6 and the I₃₄H8 in the long mixing time NOESY experiments. An inter-aromatic NOE was observed between the I₃₄H8 and C₃₅H6. However, the NOEs expected of U₃₃ and I₃₄/A₃₄ that would be attributable to a U-turn were not observed.

In the middle of the anticodon loop, the ribose resonances of C₃₅H2', H4', H5' and H5'' were strongly shifted upfield from the other ribose resonances. The C₃₅H4' and H5' resonances overlapped, but their assignments were confirmed by the natural abundance ¹H-¹³C HSQC (Fig. 3b). It is interesting to note that in ASL^{Arg1,2}_{ICG}-s²C₃₂ and ASL^{Arg1,2}_{ACG}-s²C₃₂, the C₃₅H4', H5' and H5'' upfield resonances were shifted slightly less than that of ASL^{Arg1,2}_{ICG} and ASL^{Arg1,2}_{ACG} (0.1 to 0.2 ppm). Identical upfield chemical shifts have been observed previously [46,51] and are characteristic of a sugar directly located over a base, thus experiencing a base ring current. A strong connectivity was observed between the C₃₅H5 and U₃₃H2', still observable at 50 ms (Fig. 3c), as well as a medium to weak NOE connectivity between the C₃₅H6 and U₃₃H2'. The C₃₅H5 proton exhibited strong dipolar connectivities to the A₃₄/I₃₄ H3', H5' and H5'' protons. At 400 ms, a very weak NOE could be observed between the C₃₅H6 and U₃₃H5 of the ASL^{Arg1,2}_{ICG}-s²C₃₂.

On the 3'-side of the anticodon loop, the G₃₆ exhibited a strong intra-nucleotide H8 - H1' NOE observed in the 50 ms NOE spectrum (Fig. 3c). Sequential G₃₆H1' - A₃₇H8 and G₃₆H8 - A₃₇H8 NOEs connectivities were observed in the 400 ms NOESY spectrum. More interestingly, non-sequential NOEs connectivities were observed between the G₃₆H8 and A₃₈H8, as well as between the G₃₆H1' and A₃₈H8 and between the G₃₆H8 and A₃₈H1' (Fig. 3a). G₃₆H8 exhibited NOEs with C₃₅H5'' and either or both of the C₃₅H4', H5' degenerated resonances. A protonated A₃₈ facilitates and strengthens the potential for C₃₂-A₃₈ hydrogen bonding. The A₃₈C2 connectivity was not upfield in comparison to other C2 resonances, indicating that A₃₈ was not protonated under our conditions [52]. The NOE connectivity observed between A₃₈H8 and A₃₇H1' was relatively strong and still observable in the 50 ms NOESY spectrum. However, the A₃₇H2, assigned with the help of the natural abundance ¹H-¹³C HSQC spectrum, exhibited no NOEs with other aromatics and ribose resonances, hinting at this base's orientation in regard to other nucleosides within the structure. The ASL^{Arg1,2}_{ACG-s}²C₃₂ spectrum exhibited two very weak NOEs between A₃₇H2 and A₃₈H1' and between A₃₇H2 and A₃₇H1', but these NOEs were only observable at a 400 ms mixing time. Finally, A₃₈ and C₃₉ were stacked as demonstrated by the C₃₉H5 - A₃₈H8 and C₃₉H6 - A₃₈H8 NOE connectivities. The A₃₈H2 exhibited a strong NOE connectivity with C₃₉H1', as well as a medium inter-loop NOE connectivity with U₃₃H1'.

Sugar conformations and backbone geometry. The COSY, DQF-COSY and TOCSY spectra indicated that all the nucleosides of the stem (C₂₇ - G₃₁, C₃₉ - G₄₃), except G₄₃, adopted the *C3'-endo* sugar pucker (³J_{H1'-H2'} < 2Hz) characteristic of an A-form RNA helix. Among the loop nucleosides, the s²C₃₂/C₃₂ and A₃₈ took the *C3'-endo* conformation. U₃₃ and G₃₆ exhibited a mixture of *C2'-endo*/*C3'-endo* conformation and I₃₄/A₃₄, C₃₅ and A₃₇ adopted the *C2'-endo* conformation, as suggested by their ³J_{H1'-H2'} > 5Hz. The G₃₆ sugar pucker was *C3'-endo*. The G₃₆ has a χ dihedral angle of $91.3 \pm 0.6^\circ$ and $91.8 \pm 7.4^\circ$ for ASL^{Arg1,2}_{ICG} and ASL^{Arg1,2}_{ICG-s}²C₃₂, respectively, which corresponded to the transition between the *+sc* or *+ac* conformation. The distances between G₃₆H8 and G₃₆H1' were $2.60 \pm 0.03 \text{ \AA}$ and $2.58 \pm 0.04 \text{ \AA}$ for ASL^{Arg1,2}_{ICG} and ASL^{Arg1,2}_{ICG-s}²C₃₂, respectively. The ³¹P phosphorous spectrum

showed that all the resonances are grouped together within ± 0.5 ppm except for two resonances belonging to the ^{31}P resonances of A_{38} and the $\text{A}_{34}/\text{I}_{34}$ which were downfield from the center of the main ^{31}P resonances by ~ 0.8 and ~ 0.4 ppm, respectively. All the other resonances, including the G_{36} P, C_{35} P and U_{33} P, remain in the main cluster, suggesting that the α and ζ angles are typical of A-RNA form.

2.4.3 Structure of the *tRNA*^{Arg1,2} ASLs

The structures of the four differently modified ASLs, $\text{ASL}^{\text{Arg1,2}}_{\text{ACG}}$, $\text{ASL}^{\text{Arg1,2}}_{\text{ACG-s}^2\text{C}_{32}}$, $\text{ASL}^{\text{Arg1,2}}_{\text{ICG}}$ and $\text{ASL}^{\text{Arg1,2}}_{\text{ICG-s}^2\text{C}_{32}}$, were surprisingly similar to each other, and not reflective of the conformation that would be required of their codon binding on the ribosome. The structures were determined by restrained molecular dynamics from the NMR data and were calculated using NOE restraints based on 200 and 250 ms mixing times. The ten selected lowest-energy structures for $\text{ASL}^{\text{Arg1,2}}_{\text{ICG}}$ and for $\text{ASL}^{\text{Arg1,2}}_{\text{ICG-s}^2\text{C}_{32}}$ were superimposed (Fig. 5). Relative to the mean structure, the average structures for $\text{ASL}^{\text{Arg1,2}}_{\text{ICG}}$ and $\text{ASL}^{\text{Arg1,2}}_{\text{ICG-s}^2\text{C}_{32}}$ have an overall heavy atom RMSD of 1.2 ± 0.4 Å and 1.6 ± 0.6 Å, respectively (Table 2). The stems formed the classical A-RNA helix. In the determination of hairpin RNA structures by NMR, loop nucleosides are usually less restrained than that of the stem due to a lack of NOEs. However, the RMSD of the loop nucleosides $\text{s}^2\text{C}_{32}/\text{C}_{32}$ to A_{38} are 0.6 ± 0.2 Å and 1.3 ± 0.6 Å for $\text{ASL}^{\text{Arg1,2}}_{\text{ICG}}$ and $\text{ASL}^{\text{Arg1,2}}_{\text{ICG-s}^2\text{C}_{32}}$, respectively. The somewhat higher RMSD values and errors observed for $\text{ASL}^{\text{Arg1,2}}_{\text{ICG-s}^2\text{C}_{32}}$ were probably due to the quality of the NMR spectra for the doubly modified ASL, resulting in a lower and less accurate number of NOEs distance restraints that could be used for the structure calculation. Nevertheless, we cannot rule out the possibility that the s^2C_{32} modification induced local dynamics and thus, would correlate to results of the thermodynamic studies. The anticodon loops of $\text{ASL}^{\text{Arg1,2}}_{\text{ICG}}$ and $\text{ASL}^{\text{Arg1,2}}_{\text{ICG-s}^2\text{C}_{32}}$ ($\text{s}^2\text{C}_{32}/\text{C}_{32}-\text{A}_{38}$) exhibited the same global folding with minor differences that could be attributed to differences in RMSD (Fig. 6a). Interestingly, G_{36} was stacked nicely on A_{38} consistent with the NOEs observed between these two nucleosides. The position of G_{36} was stabilized by one hydrogen bond between $\text{G}_{36}\text{N2}$ and $\text{A}_{37}\text{OP1}$ with an average acceptor donor distance of 3.29 ± 0.26 Å and 3.50 ± 0.38

Å for $ASL^{Arg1,2}_{ICG}$ and $ASL^{Arg1,2}_{ICG-s^2C_{32}}$. A₃₇ did not participate in what is the canonical 3'-stack of anticodon loop nucleosides. A₃₇ was flipped out and directly in contact with the solvent; the position of A₃₇H2 was consistent with its lack of NOE connectivities (Fig. 6a). An intra-nucleoside hydrogen bond could be detected between A₃₇O2' and A₃₇N3 (Fig. 6b). The average distance between the acceptor and donor atoms was 3.11 ± 0.10 Å for $ASL^{Arg1,2}_{ICG}$ and 3.09 ± 0.11 Å for $ASL^{Arg1,2}_{ICG-s^2C_{32}}$.

The sugar of C₃₅ was stacked below the base of G₃₆, explaining the unusual upfield chemical shifts observed for the ribose protons of C₃₅ (Fig. 6a). Moreover, the C₃₅H5 and H6 were close to I₃₄H5', H5'' and H3', consistent with the NMR data. The base of C₃₅ stacked loosely below U₃₃, in agreement with the weak NOE observed between C₃₅H5 and U₃₃H6 for $ASL^{Arg1,2}_{ICG-s^2C_{32}}$. The C₃₅ position was stabilized probably by a hydrogen bond between C₃₅N4 and A/I₃₄ O2P with an average distance between the acceptor and donor atoms of 3.67 ± 0.66 Å for $ASL^{Arg1,2}_{ICG}$ and 4.00 ± 0.85 Å for $ASL^{Arg1,2}_{ICG-s^2C_{32}}$ (Fig. 6b). The positions of I₃₄, C₃₅ and G₃₆ exposed the non-bridging phosphate oxygen atoms from C₃₅ at the top of the loop (Fig. 6a). The exposure of this oxygen atom may have important functional consequences, especially in the critical recognition of C₃₅ by the arginyl-tRNA-synthetase [53]. The s²C₃₂/C₃₂ was well stacked under U₃₃ and over the G₃₁ of the stem. The I₃₄, as well as A₃₄ in $ASL^{Arg1,2}_{ACG}$ and $ASL^{Arg1,2}_{ACG-s^2C_{32}}$, was bulged out and this position explains the absence of NOEs observed from I₃₄H₂. The loop was closed by the non-canonical A₃₈•C₃₂ base pair (Fig. 6c). However, hydrogen bonding seen here with the N6 of A₃₈ acting as a proton donor for N3 of C₃₂ (Fig. 6b,c) differs from the classically bifurcated network typically seen in which the N6 of A₃₈ acts as a dual donor for the O2 of C₃₂ only [54]. We observed one hydrogen bond between A₃₈N6 and C₃₂/s²C₃₂ N3 with an acceptor donor distance of 3.35 ± 0.43 Å for $ASL^{Arg1,2}_{ICG}$ and 3.73 ± 0.48 Å for $ASL^{Arg1,2}_{ICG-s^2C_{32}}$ (Fig. 6b). The intra-loop hydrogen bonds stabilized the loop conformation (Fig. 6d) contributing to the relative inside/outside orientation of each base (Fig. 6d).

The four differently modified $ASL^{Arg1,2}$, $ASL^{Arg1,2}_{ACG}$, and $ASL^{Arg1,2}_{ACG-s^2C_{32}}$, $ASL^{Arg1,2}_{ICG}$ and $ASL^{Arg1,2}_{ICG-s^2C_{32}}$, had similar spectral characteristics with only minor

differences, suggesting that they exhibited the same overall conformation. Indeed a superimposition of spectra for the singly modified ASL^{Arg1,2}_{ICG} and the doubly modified ASL^{Arg1,2}_{ICG-m²A₃₇} showed only slight differences which may be caused by local environmental variations associated with the methylated adenosine (Supplemental Information; Fig. S2). Yet, the resulting conformation of the anticodon loop is at odds with the conventional wisdom for anticodon structures required for tRNA's binding to cognate and synonymous codons in the A-site of the ribosome. None of the constructs exhibited the NMR characteristics of the canonical U-turn [47]. tRNA's U-turn functions to facilitate long-range tertiary interactions exposing the Watson-Crick faces of the anticodon bases to the solvent for codon binding.

2.4.4 Modifications modulate binding to non-cognate synonymous codons

The unexpected and unconventional architecture of the anticodon of the ASL^{Arg1,2}_{ICG} constructs brought into question their abilities to bind to their synonymous codons. To investigate the contribution of post-transcriptional modifications to the decoding function of the tRNA, ribosome A-site binding was assessed *in vitro* with both the cognate (CGU) and non-cognate, synonymous codons (CGC, CGA) that tRNA^{Arg1,2}_{ICG} is known to decode. All six ASL^{Arg1,2} constructs bound to the A-site cognate CGU codon with physiologically relevant binding constants (Fig. 7; Table 3). The ASLs with A₃₄, ASL^{Arg1,2}_{ACG}, ASL^{Arg1,2}_{ACG-s²C₃₄}, and ASL^{Arg1,2}_{ACG-m²A₃₇} and ASL^{Arg1,2}_{ICG} bound to CGU at approximately the same levels of saturation, 4-5 pmoles (Fig. 7a,b). The uniformity of the dissociation constants and amounts of ASL bound indicated that modifications were not necessary for efficient codon binding to the cognate codon, CGU. As would be expected, the ASL^{Arg1,2}_{ACG}, ASL^{Arg1,2}_{ACG-s²C₃₄}, and ASL^{Arg1,2}_{ACG-m²A₃₇} did not bind to the CGC or CGA codons even at levels of ASL that saturated the mRNA-programmed ribosomes (data not shown).

ASL^{Arg1,2}_{ICG} bound CGC and CGA, and ASL^{Arg1,2}_{ICG-s²C₃₄} and ASL^{Arg1,2}_{ICG-m²A₃₇} bound CGC with physiologically relevant dissociation constants (K_{d} s between 0.4 and 1.4 μ M; Table 3). However, the amount of ASL^{Arg1,2}_{ICG} maximally bound to CGU, CGC and CGA

varied with the modification under identical assay conditions (Fig. 7b-d). The maximal amount of $ASL^{Arg1,2}_{ICG-s^2C_{32}}$ and $ASL^{Arg1,2}_{ICG-m^2A_{37}}$ that bound to the cognate codon CGU was ~2 pmoles, ~50 % of that bound to CGU. Further reductions in the amount bound were observed for the binding of $ASL^{Arg1,2}_{ICG}$, $ASL^{Arg1,2}_{ICG-s^2C_{32}}$ and $ASL^{Arg1,2}_{ICG-m^2A_{37}}$ to the non-cognate synonymous codon CGC, 1.0, 0.8 and 0.4 pmoles bound, respectively. Although $ASL^{Arg1,2}_{ICG}$ was the only ASL to bind to CGA, the maximum amount bound was reduced to 1.6 pmol (Fig. 7d). The introduction of either s^2C_{32} or m^2A_{37} completely abrogated binding of the $ASL^{Arg1,2}_{ICG}$ to the non-cognate synonymous codon CGA, as evidenced by their inability to bind to the ribosome above the levels of the control mRNA codon GCG. In observing what appears to be a negative function for the s^2C_{32} and m^2A_{37} modifications of $ASL^{Arg1,2}_{ICG}$, we hypothesized that the modifications may play a role in restricting the anticodon G_{36} from binding erroneously in a wobble pair manner to the codons beginning with U_1 . However, none of the six ASLs were able to bind the UGU, UGC or UGA codons showing that G_{36} is unable to decode a uridine at the first position of the codon for any of the ASLs tested (data not shown).

2.5 Discussion

2.5.1 Modifications alter tRNA's decoding of specific codons

Previous studies have shown the importance of position 34 modifications in both expanding [4,46] and restricting [9] wobble discrimination at the third codon base. Indeed, Crick hypothesized correctly that I_{34} would expand the decoding ability of a single tRNA isoacceptor to codons ending in U, C and A [30]. Here, codon-specific ribosomal binding assays confirm this function for I_{34} in *E. coli* $ASL^{Arg1,2}$. The singly modified $ASL^{Arg1,2}_{ICG}$ bound all three synonymous codons with low micromolar binding constants and the unmodified ASL was unable to bind either of the two non-cognate synonymous codons CGC or CGA. Free energy calculations of base pairing with inosine suggest that the purine•purine pair of $I_{34}\bullet A_3$ should be significantly less favorable than $I_{34}\bullet U_3$ or $I_{34}\bullet C_3$ [55]. The binding constants demonstrated that the $ASL^{Arg1,2}_{ICG}$ constructs had no preference among the three

bases, U, C and A, at the third codon position. However, the maximal amount of ASL bound varied. In binding CGU in which the I₃₄•U3 pair is formed, the amount of ASL bound exceeded the binding of the CGC and CGA codons by ~1.7 fold. These results confirmed the physiological relevance of the crystal structures of a singly modified ASL^{Arg1,2}_{ICG} bound to CGC and CGA in the ribosomal A-site [56] and support *in vivo* assays showing the inefficiency of the I₃₄•A3 wobble base pair in recognition of CGA [57].

The ASL^{Arg1,2}_{ICG-s²C₃₄} and the ASL^{Arg1,2}_{ICG-m²A₃₇} were capable of decoding only CGU and CGC. A-site binding of CGA was undetectable for these doubly modified ASL^{Arg1,2}_{ICG}. The lack of codon binding by ASL^{Arg1,2}_{ICG-m²A₃₇} was in accord with S1 nuclease cleavage experiments that showed that the ASL exhibits characteristics unlike that of a canonical U-turn-containing isoleucyl-tRNA [37]. The presence of s²C₃₂ caused a significant change in nuclease accessibility to the anticodon domain, albeit in the direction of a cleavage pattern more similar to tRNA^{Ile}, but still lacked the signature pattern consistent with a U-turn conformation [37]. The ASL^{Arg1,2}_{ICG-s²C₃₂} and ASL^{Arg1,2}_{ICG-m²A₃₇} exhibited a significant reduction in the amount of ASL maximally bound to CGU and CGC in comparison to that of the singly modified ASL^{Arg1,2}_{ICG} construct. Taken together, these results could be interpreted as modifications causing a shift in the conformational equilibrium to a more populated, but unfavorable, structure for codon binding. However, non-denaturing PAGE, NMR structure determination and NMR gradient diffusion results conclusively showed a highly populated singular, monomolecular conformation in solution for all constructs.

In order for the ASL to adopt the necessary geometry for the purine•purine (I₃₄•A3) pair during CGA decoding, the anticodon bases need to have a larger amount of allowed conformational space than is required for binding to CGU or CGC. Also, the anticodon must be able to overcome the elevated energy barrier between the unpaired and paired states [55]. The higher level of loop rigidity indicated by circular dichroism for doubly modified ASL^{Arg1,2}_{ICG-m²A₃₇} would most likely reduce the conformational space of the anticodon, similarly to how a methylated guanosine, in combination with a modified cytidine at position 32 and a modified purine at position 34, in ASL^{Phe} restricts the ASL conformational space

[44]. Chemical synthesis of the fully modified ASL^{Arg1,2}_{ICG-s²C₃₄;m²A₃₇} was problematic, but perhaps if tested, it would be able to recognize CGA in its fully modified state.

2.5.2 ASL^{Arg1,2} constructs form a similar but unconventional solution structure

The anticodon loops of the variously modified ASL^{Arg1,2}, had the same overall, but unexpected structural characteristics (Fig. 8a). Chemical shift differences between constructs did not appear significant. A very slight change in base stacking would have been observed as a dramatic change in chemical shift [58]. The anticodon loops of the doubly modified ASLs may be more dynamic than that of the singly modified ASLs. The unmodified and modified ASL^{Arg1,2} constructs bound cognate and synonymous codons in solution with physiologically relevant binding constants. However, the ASL^{Arg1,2} solution structures adopted a ⁵UNCG³ tetraloop conformation [59,60], and not that of the canonical U-turn (Fig. 6b). In a tetraloop conformation, the 3'-terminal G adopts the *syn* conformation with a C3'-*endo* sugar pucker. The tetraloop G is base paired with uridine and the majority of time adopts the classical wobble G•U base pair. The interaction is characterized by a very intense NOE between the GH1 and the UH3 imino protons as observed in the water NOESY spectra (distance ~ 2.5 Å). The N nucleoside of the ⁵UNCG³ motif is pulled out and adopts the C2'-*endo* sugar conformation. Finally, this tetraloop is closed by a Watson-Crick base pair. The ASL^{Arg1,2} constructs have the ⁵U₃₃(A/I₃₄)C₃₅G₃₆³ primary sequence of the ⁵UNCG³ motif and are 'closed' by the non-canonical s²C₃₂/C₃₂•A₃₈ base pair (Fig. 7c). The A/I₃₄ is pulled outside (Fig. 7d) and adopts the C2'-*endo* sugar conformation usually observed in the ⁵UNCG³ motif [59]. Nevertheless, the strong GH1-UH3 NOE connectivity of the classical ⁵UNCG³ tetraloop was not observed due to distances between the G₃₆H1 and U₃₃H3 being on average 5.65 ± 0.84 Å and 5.60 ± 0.51 Å for ASL^{Arg1,2}_{ICG-s²C₃₂} and ASL^{Arg1,2}_{ICG}, respectively. In the solution structure of the ASL^{Arg1,2}_{ICG-s²C₃₂}, G₃₆ was stacked with A₃₈ and A₃₇ was turned out emphasizing the potential importance of the m²A₃₇ and other position 37 modified nucleotides on the structure of the anticodon loop. However, NMR spectra of the ASL^{Arg1,2}_{ICG-m²A₃₇} reflected the same unusual structural characteristics as ASL^{Arg1,2}_{ICG-s²C₃₂} and ASL^{Arg1,2}_{ICG} (Supplemental Information, Fig. S2). Thus, the m²A₃₇ modification alone

was unable to change the loop conformation. It is tempting to speculate that both modified nucleotides in position 32 and 37 could play an important role in destabilizing the pseudo $5^{\prime}\text{UNCG}3^{\prime}$ conformation observed and thereby induce formation of the U-turn. The results reported in this work favor such an interpretation because of the unusual destabilization by $s^2\text{C}_{32}$. Indeed, the S1 nuclease digestion experiments of fully modified $\text{tRNA}^{\text{Arg1}}$ showed a pattern more indicative of a U-turn. However, the accessibility between positions 36 and 37 indicated that this would still not conform to the fully canonical conformation [37]. This nuclease digestion pattern could be indicative of the tRNA's conformational dynamics rather than that of a single dominant structure at equilibrium.

The lack of NMR resonances that were indicative of a conventional U-turn, and the unique presence of the thio-modification of $s^2\text{C}_{32}$ in the tRNA^{Arg} isoaccepting species and in tRNA^{Ser} prompted us to investigate the possible contribution of divalent metal ions to the anticodon loop structure. The metal-ion binding properties of the $\text{ASL}^{\text{Arg1,2}}_{\text{ACG}}$ and $\text{ASL}^{\text{Arg1,2}}_{\text{ICG}}$ were investigated using Mg^{2+} and cobalt hexamine, $[\text{Co}(\text{NH}_3)_6]^{3+}$, as a model for the biologically relevant $[\text{Mg}(\text{H}_2\text{O})_6]^{2+}$ ligand (Supplemental Information, Fig. S3 [61-63]). Titration of the RNA with magnesium or cobalt ions broadened most of the ^1H -NMR resonances. The ^{31}P spectra indicated that the metal ions induced some conformational changes in the ASL, but not toward the U-turn conformation. The chemical shift dispersion of the ^{31}P resonances narrowed around the A-form RNA (Supplemental Information, Fig. S3), whereas in the U-turn conformation there is a strong downfield signal separated from the other A-form ^{31}P resonances [46,47].

The solution structures of the variously modified $\text{ASL}^{\text{Arg1,2}}$ can be compared to the crystal structures of the yeast $\text{tRNA}^{\text{Arg1,2}}_{\text{ICG}}$ with its cognate arginyl-tRNA synthetase [53], and that of $\text{ASL}^{\text{Arg1,2}}_{\text{ICG}}$ on the ribosome bound to A-site codons (Fig. 8b [56]). The yeast $\text{tRNA}^{\text{Arg1,2}}_{\text{ICG}}$ has the same anticodon loop sequence as that of the *E. coli* $\text{tRNA}^{\text{Arg1,2}}$. In the crystal structure in complex with the synthetase, the anticodon loop is completely distorted by the protein's interaction (Fig. 8b [53]). A_{38} is pulled outside of the loop while C_{32} forms a cross-loop stack with A_{37} and thus, there is no possibility for a base pair between A_{38} and C_{32}

[53]. The anticodon's C₃₅ is an identity determinant and is recognized by the synthetase through the protein's backbone interactions of histidine residues 22 and 23, and a stacking interaction with tryptophan 569. The structure of the ASL^{Arg1,2}_{ICG} bound to codon in the ribosomal A-site [56] differs significantly from that bound to the synthetase. All the ASL^{Arg1,2}_{ICG} loop nucleosides adopted the *C3'-endo* conformation, and the loop adopted the classical U-turn conformation expected for codon recognition with the stacking of the anticodon I₃₄C₃₅G₃₆ (Fig. 8b). Additionally, A₃₈ is positioned inside the loop in close enough proximity to C₃₂ to allow for a cross loop interaction. It is interesting to note that the geometry of the C₃₂•A₃₈ interaction seen in these crystal structures shifts depending on whether CGC or CGA is present in the ribosomal A-site. When bound to CGC, the interaction consists of a single hydrogen bond between C₃₂N3 and A₃₈N6, whereas binding to CGA results in a conformational shift of C₃₂ such that a hydrogen bond forms between C₃₂O2 and A₃₈N6 [56]. A very similar, although not as drastic, conformational shift is seen in our solution structures, albeit, not from the presence of a codon, but from the introduction of s²C₃₂ to ASL^{Arg1,2}_{ICG} (Fig. 7c). Indeed, it has been shown that the nature and geometry of the C₃₂•A₃₈ base pair can directly alter the affinity for both cognate and wobble codons [64]. When the adenosine is protonated, C₃₂•A⁺₃₈, even at a pH of 6.5, the ASL is stabilized [52]. The presence of a U₃₂ allowed a tRNA to discriminate between different codons, reducing the ability of the tRNA to recognize codons with the third position wobble base [64]. However, mutating U₃₂ to a C₃₂ restored the wobble decoding ability. In our structures, the introduction of s²C₃₂ to ASL^{Arg1,2}_{ICG} shifted the conformation toward a geometry more similar to the U₃₂•A₃₈ pair [65]. This modification modulated change in conformation is in agreement with our binding data and indicative of a role for s²C₃₂ in discriminating wobble base pairing to CGA.

The NMR structure of the free ASL^{Arg1,2}_{ICG} differed considerably from the crystal structures where the ASL of tRNA^{Arg1,2}_{ICG} was bound to the cognate synthetase [53] or to the mRNA codon in the ribosome [56]. The solution structures of the variously modified ASL^{Arg1,2}_{ICG} are more like each other (Fig. 8a) than the disparate crystal structures with the

arginyl-tRNA synthetase and bound to codon on the ribosome (Fig. 8b). Therefore, three significantly different conformations have been observed for the anticodon domain of the tRNA^{Arg1,2} isoacceptors in recognition of the identity determinant of C₃₅ by the arginyl-tRNA synthetase, in solution and with various modified nucleosides, and on the ribosome in response to the codons CGC and CGA. Since the ASL adopts a U-turn in the ribosomal A-site and highly distorted conformation when bound to the synthetase, these macromolecules must induce structural changes in the loop requiring a certain degree of conformational space. In this case, the modifications may imbue a certain degree of flexibility or deformability to the loop which would either allow or disallow the adoption of each of the necessary conformations. Structural differences also exist between the solution and ribosome-bound structures of fully modified hASL^{Lys3}; however, these differences are small due to the inherent U-turn solution structure induced by the loop modifications (F.A.P. Vendeix and P.F. Agris, personal communication).

2.5.3 Modifications modulate anticodon domain dynamics for most effective codon usage

The Modified Wobble Hypothesis suggests that a key role for anticodon domain modifications is to alter or pre-structure the anticodon loop conformation into a U-turn, permitting proper geometry of the anticodon bases for codon recognition in the ribosomal A-site [66]. Indeed, the combination of modifications at positions 32, 34 and 37 have been shown to pre-form the anticodon loop into a U-turn conformation in many cases [4,45,46,67,68]. While examples of unmodified ASLs that can bind to cognate codons can be found, they all show spectral characteristics of a U-turn conformation [46]. The solution structures of the ASL^{Arg1,2} constructs, coupled with the ribosome binding results signify the first instance of an ASL with a conformation showing no U-turn indicators that has the ability to efficiently bind codons in the ribosomal A-site.

Codon binding assays and structural characterizations of ASL^{Arg1,2} demonstrated that there are clear functional differences between differently modified ASLs though their solution structures are quite similar (Fig. 8a). Surprisingly, structural analysis showed that none of the

three modifications altered the solution structure significantly from the highly stable $5' \text{UNCG}^{3'}$ motif seen in the unmodified ASL. Also, the singly modified $\text{ASL}^{\text{Arg1,2}}_{\text{ICG}}$ efficiently decodes CGA, whereas $\text{ASL}^{\text{Arg1,2}}_{\text{ICG-s}^2\text{C}_{32}}$ and $\text{ASL}^{\text{Arg1,2}}_{\text{ICG-m}^2\text{A}_{37}}$ cannot. This functional difference cannot be explained by structural differences as these ASLs contain the same chemical modification at position 34 (inosine) and have nearly identical solution structures. Also, the structural results cannot explain the differences in S1 nuclease accessibility seen with the addition of s^2C_{32} ; however, this may be due to different solution conditions (25 mM sodium acetate, pH 4.5, 5 mM MgCl_2 , 50 mM KCl and 1 mM zinc acetate) used during those studies [37]. There is precedence for structural features that do not explain functional differences in the anticodon domain of tRNA. Biophysical and structural characterization indicate that the methylated guanosine (m^1G_{37}) in yeast ASL^{Phe} causes a slight destabilization of the stem and coordinates the loop, allowing for a more defined $\text{Cm}_{32} \bullet \text{A}_{38}^+$ cross loop pair, restricting the conformational space of the anticodon [5,37].

Here, we have shown that $\text{ASL}^{\text{Arg1,2}}$ modifications do not contribute appreciably to the anticodon's conformation at equilibrium, and that the modifications do not alter the equilibrium solution structure toward either of the two conformations seen in the crystal structures. However, the modifications caused significant differences in the dynamics and stability of the molecule. Thermal denaturation of the ASLs showed that s^2C_{32} alone caused a considerable reduction in thermal stability as indicated by a low T_m ($\Delta T_m = -5 \text{ }^\circ\text{C}$) and increased free energy of folding ($\Delta\Delta G = +1.93 \text{ kcal/mol}$) compared to the unmodified ASL. The s^2C_{32} and m^2A_{37} decreased base stacking interactions, as determined from a reduction in the ASLs hyperchromicity. The small differences in ellipticity in the CD spectra and yet large reductions in thermal stability could be explained by the proximity of the s^2C_{32} loop modification to the stem. As suggested previously, this is a clear example that the structural and dynamic contributions of anticodon modifications cannot be ascertained by summing up the contributions of the individual nucleosides [44]. The differently modified $\text{ASL}^{\text{Arg1,2}}_{\text{ICG}}$, $\text{ASL}^{\text{Arg1,2}}_{\text{ACG-s}^2\text{C}_{32}}$ and $\text{ASL}^{\text{Arg1,2}}_{\text{ACG-m}^2\text{A}_{37}}$ and the doubly modified $\text{ASL}^{\text{Arg1,2}}_{\text{ICG-s}^2\text{C}_{32}}$ and $\text{ASL}^{\text{Arg1,2}}_{\text{ICG-m}^2\text{A}_{37}}$ constructs differed in thermal stability and in their abilities to bind

cognate and synonymous codons. These ASLs may have a large energy barrier to overcome during a shift from the $5' \text{UNCG} 3'$ conformation seen in solution to the U-turn motif needed for codon binding or the odd conformation in binding to the arginyl-tRNA synthetase. A higher energy barrier between functional conformations would be in agreement with the observation that reduced amounts of the ASL^{Arg1,2}_{ACG-s²C₃₂} and ASL^{Arg1,2}_{ACG-m²A₃₇} were found bound to CGU and CGC. This coupled with the unusually high energy barrier for the I₃₄•A₃ base pair would sufficiently explain the inability to bind to the CGA codon. Thus, the anticodon domain modifications in tRNA^{Arg1,2} may function by lowering an energy barrier between the solution structure and the two drastically different conformations needed for binding to the synthetase [53] and to the ribosome [56]. The inability of the ASL to efficiently bind to CGA codons may be a side effect of this need to modulate the energy barrier between conformations, causing CGA to be used less often in *E. coli* coding sequences.

Codon usage in *E. coli* and *Saccharomyces cerevisiae* has been directly related to the relative content of individual tRNA species within the cell [56,69]. In the case of *E. coli* tRNA^{Arg1,2}, the recognition of the codons CGU, CGC and CGA, differing in usage from between 21.0 for CGC to 3.9 for CGA per 1000 codons [70], is accomplished using a single set of isoacceptors. Interestingly, we found that the ability of the differentially modified ASL^{Arg1,2}_{ICG} to bind these three codons mimicked the codon usage in *E. coli* (Supplemental Information, Table S2). For the two codons, CGU and CGC, that are more frequently used, 20.4 and 21.0 per 1000 codons respectively [70], all three of the inosine-containing ASLs were able to bind the codons efficiently *in vitro*. However, for CGA (3.9 per 1000 codons) only the singly modified ASL^{Arg1,2}_{ICG} bound efficiently. This suggests a role for s²C₃₂ and m²A₃₇ in restricting codon recognition by ASL^{Arg1,2}_{ICG} to CGU and CGC. A modification-dependent mechanism of selective codon binding, as suggested by these results, would allow a single tRNA species to have vastly different codon usage dependent on the proportion of anticodon domain modifications at nucleosides 32, 34 and 37. The modification state of the tRNA acts as the regulator of codon recognition. This would suggest a role for these

modifications in ASL^{Arg1,2}_{ICG} in particular in regulating the expression of the genes which may be necessary for certain environmental, stress or growth conditions. Precedence for tRNA modification as a regulator of decoding in response to cellular stress has been shown for tRNA methylation in yeast [71]. Further studies, including a characterization of fully modified ASL^{Arg1,2}_{ICG}, would provide evidence to decipher the mechanisms by which s²C₃₂ and m²A₃₇ negate CGA binding, while allowing an induced U-turn conformation in the ribosomal A-site for the binding of CGU and CGC. Post-transcriptional nucleoside modifications in the anticodon loop of *E. coli* ASL^{Arg1,2} contribute functional significance to the decoding of the cognate and synonymous codons during protein synthesis.

2.6 Materials and methods

2.6.1 Oligonucleotide preparation

The modified nucleoside 2-thiocytidine (s²C) was synthesized (Trilink Biotechnologies, San Diego, CA) and then derivatized to the 5'-*O*-[benzhydryloxybis(trimethylsilyloxy)silyl]-2'-*O*-[bis(2-acetoxyethoxy)methyl]-2-thiouridine-3'-(methyl-*N,N*-diisopropyl)- phosphoramidite, the 'ACE' protected phosphoramidite (Thermo Fisher, Dharmacon Products, Lafayette, CO). The s²C₃₂-containing heptadecamer constructs were synthesized with or without I₃₄ (Thermo Fisher, Dharmacon Products, Lafayette, CO). The chemically synthesized unmodified and inosine containing ASLs also were produced by ACE chemistry.

Chemical synthesis of 2-methyladenosine was accomplished using a previously described procedure [72-74]. Peracetylated guanosine was chlorinated to give 2-amino-6-chloro-9-(2',3',5'-tri-*O*-acetylribofuranosyl)purine and then converted to 2-iodoadenosine. Following methylation with trimethylaluminium, in the presence of palladium catalyst gave 2-methyladenosine [75]. The exocyclic amine function of m²A was protected with a benzoyl group using transient protection methodology [73]. *N*⁶-benzoyl-2-methyladenosine was then

protected with DMTr and TBDMS on the 5' and 2' hydroxyls and phosphitylated to give the fully protected 3'-*O*-phosphoramidite [76]. Modified 2-methyladenosine units were supplied to IDT (formerly RNA-Tec, Belgium) for synthesis of 2-methyladenosine-modified ASLs with and without I₃₄.

After deprotection via standard protocol, RNA was purified by preparative anion-exchange HPLC, desalted and dialyzed extensively against 20 mM sodium phosphate buffer, pH 6.8 and 0.05 mM EDTA using a 3500 Da cutoff membrane. For observations of the exchangeable protons, the samples were resuspended in 300 μ L of 90 % H₂O/ 10 % D₂O. For experiments involving the non-exchangeable protons, the samples were exchanged twice with 99.9 % D₂O. The NMR sample concentrations were between 0.8 and 1.2 mM.

2.6.2 Native polyacrylamide gel electrophoresis

Global conformational differences between the variously modified ASLs were determined by native polyacrylamide gel electrophoresis (PAGE). An 18 % (w/v) polyacrylamide gel was prepared in pH 8.3 tris borate (TB) buffer (89 mM Tris base, 89 mM boric acid). RNA samples (30 μ M in 12 μ L total volume) were in loading buffer (5 % [w/v] glycerol, 0.04 % [w/v] bromophenol blue and 0.04 % [w/v] xylene cyanol FF in TB buffer). All samples were heated to 85 °C for 2 minutes and allowed to cool at room temperature for 30 minutes prior to loading. Electrophoresis was performed at 4 °C using a temperature controlling apparatus (Novex Mini-cell Thermoflow, Invitrogen) followed by subsequent staining in 0.5 μ g/mL ethidium bromide. Gel results were recorded with a BioRad Imager running Quantity One software.

2.6.3 Thermal denaturation spectroscopy

Thermal denaturation and renaturation of the ASLs was monitored by UV absorbance at 260 nm using a Varian Cary 3 UV-visible spectrophotometer running Thermal software [6,44]. All samples were analyzed at an optical density of \sim 0.2 A₂₆₀/ml (ambient temperature) in 20 mM sodium phosphate buffer at pH 6.8. The temperature was ramped at 1

°C/min from 7 - 92 °C. Absorbance data was collected at a rate of 4 data points per minute. Thermodynamic properties were determined with MeltWin v3.5 software. All experiments were performed simultaneously with a control cell containing buffer only and this data was subtracted as the background prior to analysis. Data from a minimum of five denaturations and renaturations were averaged and the error was calculated as the standard error of the mean. Optical melting experiments were performed at different pH values (pH = 6.0, 6.8 and 7.2) for the unmodified ASL^{Arg1,2}_{ACG} and results were found to be independent of pH within that range (data not shown).

2.6.4 Circular dichroism spectroscopy

Circular dichroism (CD) spectra were collected on a Jasco J600 spectropolarimeter. All samples were adjusted to ~0.2 A₂₆₀/ml (ambient temperature) in 20 mM sodium phosphate buffer (pH 6.8) prior to CD analysis and analyzed in a 1 cm path length quartz cuvette. Samples were temperature controlled to 5 ± 1 °C during data collection. All data were baseline corrected using a control containing buffer only. Data was analyzed by normalizing the spectra to molar circular dichroic absorbance using simultaneously collected absorbance data to calculate the concentrations of each sample ($\Delta\epsilon = \theta/32980 \cdot C \cdot L \cdot N$ [77]). Spectra shown are the averaged results of three independent experiments each consisting of triplicate data collection.

2.6.5 Ribosomal A-site codon binding assays

Sucrose density gradient centrifugation was used to purify tight-coupled 70S ribosomes from *E. coli* MRE 600 cells [78]. The mRNAs were designed as 27-mer derivatives of T4 gp32 mRNA [79]. Each mRNA sequence was analyzed by UNAFold [80] to ensure a low probability of stable secondary structure. The mRNA oligos were then purchased from Dharmacon (Thermo Scientific), deprotected and purified by dialyzing extensively against 20 mM sodium phosphate buffer (pH 6.8) using a 3500 Da cutoff membrane. The following

three mRNA oligos were used for this study with the adjacent P-site and A-site codons bolded and underlined:

(i) 5' – GAAAAGGAGGUAAAA**AUGCGUG**CACAU – 3'

(ii) 5' – GAAAAGGAGGUAAAA**AUGCGCG**CACAU – 3'

(iii) 5' – GAAAAGGAGGUAAAA**AUGCGAG**CACAU – 3'

The 17-mer ASL constructs were 5'-end ^{32}P -radiolabeled using ^{32}P - γ -ATP (MP Biomedical) and polynucleotide kinase (New England Biolabs). Radiolabeled ASLs were then purified using preparative 15 % PAGE with 7 M urea as a denaturant. Assays were performed using a constant amount of ribosome (250 nM, 5 pmoles per reaction) and increasing concentrations of unlabeled ASL (0, 0.25, 0.5, 1.0, 1.5, 2.5, 5 μM) spiked with a corresponding amount of radiolabeled ASL to a maximum of 2000 CPM at the 5 μM level [46]. All reaction mixtures were prepared in ribosome binding buffer (50 mM HEPES, pH 7; 30 mM KCl; 70 mM NH_4Cl ; 1 mM DTT; 100 μM EDTA; 20 mM MgCl_2 adjusted to pH 7 with 2 M NaOH). Ribosome mixtures were activated at 42 °C for 10 min, cooled to 37 °C and programmed with 2.5 μM mRNA for 15 min at 37 °C. Mixtures were then incubated for 15 min with $\text{tRNA}^{\text{fMet}}$ to saturate the P-site and ensure that ASL binding corresponds exclusively to A-site codon binding. ASL was then added to each reaction and incubated at 37 °C for 60 minutes, then placed directly on ice for 30 minutes. Ice cold ribosome binding buffer (100 μL) was then added to the 20 μL reaction mixtures and immediately filtered through a nitrocellulose filter with vacuum using a modified Micro-Sample Filtration Manifold (Whatman Schleicher & Schuell Minifold) 96-well dot blot apparatus [81]. The filter was then washed twice with 150 μL ribosome binding buffer in each well, removed from the apparatus and allowed to dry. A small strip of nitrocellulose was spotted with known amounts of ASL mixture to generate a standard curve for calculating pmoles bound from the intensity measurements. Filters were exposed to a phosphor screen and scanned using a Molecular Dynamics phosphor imager (GE Healthcare). The radioactive density of the spots was measured using ImageQuant software (Amersham). Mismatch mRNA (GCG

A-site codon) was used to determine nonspecific binding for each experimental data point. These values were subtracted from the experimental data to generate binding curves. Dissociation constants were then determined using the one-site specific binding equation in Prism v.3 (Graphpad). All results are the compilation of at least two independent experiments performed in triplicate with an internal standard binding assay using ASL^{Phe} with polyU as the mRNA performed in parallel. Ribosome activity and mRNA programming were determined by 5' ³²P-labeling the mRNAs and testing the efficiency by filter ribosome binding. All mRNAs showed similar binding indicative of high ribosome activity.

2.6.6 NMR spectroscopy

Solution and temperature conditions used for spectra collection with the RNA samples were those required and widely used for determination of RNA hairpin structures [10,33,46]. NMR spectra were collected on a DMX Bruker 500 MHz instrument equipped with a triple-resonance ¹H, ¹³C, and ¹⁵N probe and three-axis pulsed field gradient capabilities and on a Varian INOVA 600 MHz instrument equipped with a cryoprobe. All NMR data were processed using NMRPIPE [82]. Spectra were displayed and analyzed using SPARKY software [83]. NOESY spectra in D₂O were recorded at 10, 25 and 30°C with mixing time of 50, 100, 150, 200, 250, 300 and 400 ms. TOCSY, COSY and DQF-COSY experiments were acquired at 25°C. Natural abundance ¹H-¹³C HSQC and ¹H-³¹P HETCOR experiments were recorded in D₂O at 25°C. For the study of exchangeable protons, 2D 1H-1H NOESY spectra were recorded at different temperatures (5, 10, 25 and 30 °C) with mixing times of 125, 150 and 250 ms. To determine if, in solution, under NMR conditions, we have an hairpin or a duplex conformation, the translational diffusion constants of the ASLs were determined and compared to a 17mer ASL of the *E. coli* tRNA^{Val}, a 24mer RNA and a 56mer double stranded RNA (112mer total). This was accomplished with the pulsed field-gradient spin-echo technique [84,85] performed on the NMR sample. The translational diffusion coefficients of the three different ASL^{Arg1,2} are comparable to the ASL^{Val} and larger than the translational diffusion coefficient for the 24mer and the 56mer double stranded RNAs (Supplemental Information, Table S1). Our results are in good agreement with published

values of the translational diffusion coefficients of nucleic acids with similar sizes [86] and demonstrated that, under the conditions of our study, we have a hairpin conformation and a monomer in solution.

2.6.7 NMR restraints and structure calculation

NMR data collected at 25 and 30 °C were used for structure calculations. The NOE cross-peaks were integrated using the peak fitting Gaussian function and volume integration in SPARKY software. The distance for each cross peak was calculated and normalized to the non-overlapped pyrimidine H5-H6 cross-peaks (2.42 Å). Upper and lower bonds were assigned to $\pm 20\%$ of the calculated distances. For the overlapped peak, the cross-peaks were qualitatively classified as strong (3.0, 1.2, 0.0), medium (4.0, 2.0, 0.0), weak (5.0, 3.0, 0.0) or very weak (6.0, 3.0, 0.0 or 7.0, 3.0, 0.0). No internucleotide restraints were used from the H5' and H5'' proton connectivities. For restraints involving imino protons, the intervals (3.0, 1.2, 0.0) and (5.5, 3.5, 0.0) were used. A total of 253 and 231 distance restraints were used for the structure generation of ASL^{Arg1,2}_{ICG} and ASL^{Arg1,2}_{ICG-s²C₃₂}, respectively. Consistent with the NMR data, the five base pair stem formed Watson-Crick base pairs and they were subjected to six and four hydrogen-bond restraints for G•C and U•A base pairing, respectively, with 2.7 - 3.5 Å between the acceptor and donor atoms. Dihedral constraints on the ribose ring and backbone were derived from semi-quantitative measurement of ³J_{H-H} and ³J_{H-P}. Unobserved NOEs or “unoes” were used to separate protons for which NOEs were not observed [87].

Sugar pucker conformations were derived from the observation of the COSY and DQF-COSY spectra. Nucleosides with H1'-H2' couplings >5 Hz were constrained to the C2'-endo (δ : 160 \pm 20°), whereas nucleosides with absent or very weak H1'-H2' connectivity on the COSY spectra were constrained to the C3'-endo conformation (δ : 85 \pm 20°). Nucleosides with ³J_{H1'-H2'} between 2 and 5 Hz were left unrestrained. An independent confirmation of the sugar pucker conformation was derived from the ¹H-¹³C HSQC spectra and the C1' resonance shift upfield to the main cluster. The sugar pucker conformation was also

confirmed from the C3' and C4' resonances downfield from the respective main cluster. The γ torsion angle was derived from the ${}^3J_{H4'-H5'}$ and ${}^3J_{H4'-H5''}$ peaks in the COSY and DQF-COSY. For those nucleosides not exhibiting H4'-H5' and H4'-H5'' peaks ($J < 5$ Hz), γ was constrained to the g^+ conformation ($54 \pm 20^\circ$). For all other nucleosides, γ was left unrestrained.

The β dihedral angles were derived from the observation of ${}^3J_{P-H5'}$ and ${}^3J_{P-H5''}$ couplings on the 1H - ${}^{31}P$ HETCOR NMR spectrum. When the ${}^3J_{P-H5'}$ and ${}^3J_{P-H5''}$ were clearly absent, β was constrained to the *trans* conformation ($178 \pm 20^\circ$). When ${}^3J_{P-H5'}$ and ${}^3J_{P-H5''}$ could be observed, β was left unrestrained. All H3'-P were clearly identified on the 1H - ${}^{31}P$ HETCOR (${}^3J > 5$ Hz), therefore the ϵ dihedral angle was loosely constrained to avoid the sterically forbidden g^+ conformation ($-120 \pm 120^\circ$). Dihedral angle restraints for α and ζ were derived from the observation of the ${}^{31}P$ chemical shifts. All ${}^{31}P$ resonances, except A₃₈P and to a lesser extent A/I₃₄, were in a defined range of chemical shift. Thus, the α and ζ were constrained to avoid the *trans* conformation that result in strongly downfield ${}^{31}P$ resonances ($0 \pm 120^\circ$). A₃₈P α and ζ were left unrestrained. Each of the intra-aromatic to H1' NOE connectivities of the different ASLs nucleosides had an intensity significantly less than that of the H5-H6 NOE connectivity showing that all the bases, with the exception of G₃₆, adopted an *anti*-glycosidic torsional angle. Thus, the χ glycosidic dihedral angles were constrained to the *anti*-conformation for all nucleosides ($-158 \pm 20^\circ$), except for G₃₆ which was left unrestrained.

Molecular modeling of the ASL^{Arg1,2} anticodon stem and loop structures was achieved using CNS 1.2 [88,89]. One hundred structures were calculated using the standard NMR restrained annealing protocol [90]. The 10 structures of the lowest total energy, without dihedral or distance restraint violations, were chosen for further analysis. The helical parameters were analyzed using X3DNA software [91]. The output structures were visualized with MOLMOL [92] and PYMOL [93].

2.6.8 Accession numbers

The atomic coordinates and structural factors for the ASLs were deposited in the protein data bank (PDB) under the accession numbers 2KRP (ASL^{Arg1,2}_{ACG}), 2KRQ (ASL^{Arg1,2}_{ICG}), 2KRV (ASL^{Arg1,2}_{ICG-S²C₃₂}) and 2KRW (ASL^{Arg1,2}_{ACG-S²C₃₂}).

2.7 Acknowledgements

The authors would like to express gratitude to William Graham for HPLC purification of ASL construct, as well as Drs. Kun Lu, Jessica Spears and Caren Stark for productive conversations regarding the project and critical reading of the manuscript. This work was supported in part by a National Science Foundation grants to P.F.A. (MCB-0548602; MCB-1101859), and by Poland's National Science Centre to G.L. (1306/B/2011/40).

2.9 Tables and figures

Table 1. Thermal stability and thermodynamic properties^a of the six ASL^{Arg1,2} constructs.

ASL ^{Arg1,2}	ΔH (kcal/mol)	ΔS (cal/K* <i>mol</i>)	ΔG_{37} (kcal/mol, 37°C)	T_m (°C)	Hyperchromicity (%)
ACG	-45.9 ± 0.4	-135.2 ± 1.1	-3.92 ± 0.02	66.0 ± 0.1	16.9 ± 0.7%
ACG-s²C₃₂	-27.4 ± 0.1	-82.1 ± 0.3	-1.99 ± 0.02	61.2 ± 0.2	17.1 ± 0.4%
ACG-m²A₃₇	-45.2 ± 1.0	-133.3 ± 2.9	-3.80 ± 0.13	65.8 ± 0.6	11.2 ± 0.2%
ICG	-39.7 ± 0.4	-116.9 ± 1.2	-3.48 ± 0.04	66.8 ± 0.2	14.5 ± 0.6%
ICG-s²C₃₂	-38.6 ± 1.7	-114.7 ± 5.1	-2.99 ± 0.10	63.1 ± 0.5	12.7 ± 0.6%
ICG-m²A₃₇	-40.4 ± 1.6	-119.7 ± 4.6	-3.30 ± 0.15	64.5 ± 0.5	12.6 ± 0.2%

^aDetermined from curve fitting analysis of thermal denaturation curves using MeltWin v3.5 (Fig. 2). All errors are reported as standard error of the mean.

Table 2. Structural statistics for tRNA^{Arg1,2}_{ICG} and tRNA^{Arg1,2}_{ICG-s²C₃₂} ASLs.

Restrains	Number of empirical restraints	
	ASL ^{Arg1,2} _{ICG}	ASL ^{Arg1,2} _{ICG-s²C₃₂}
Distance restraints	253	231
<i>Intranucleotides</i>	123	112
<i>Internucleotides</i>	116	106
<i>Exchangeable</i>	6	6
<i>Unoes^a</i>	7	7
Restrains by residue	14.8	13.5
Hydrogen bonding distances restraints	28	28
Dihedral restraints	94	93
Heavy atoms RMSD^b from mean structure	Angstroms (Å)	
All residues (C₂₇ - G₄₃)	1.2 ± 0.4	1.6 ± 0.6
Loop residues (s²C₃₂/C₃₂ - A₃₈)	0.6 ± 0.2	1.3 ± 0.6

^aUnoes refers to unobserved NOEs.

^bRoot mean square deviation (RMSD) errors are reported as one standard deviation.

Table 3. Dissociation constants of the six ASL^{Arg1,2}.

ASL ^{Arg1,2}	^a K _d = μM		
	CGU	CGC	CGA
ACG	0.70 ± 0.2	N/A	N/A
ACG-s ² C ₃₂	0.70 ± 0.1	N/A	N/A
ACG-m ² A ₃₇	1.30 ± 0.2	N/A	N/A
ICG	0.88 ± 0.2	0.66 ± 0.2	0.53 ± 0.1
ICG-s ² C ₃₂	0.77 ± 0.3	0.38 ± 0.2	N/A
ICG-m ² A ₃₇	1.40 ± 0.2	0.53 ± 0.5	N/A

^aDissociation constants, *K_d*, (μM) derived from ribosomal A-site codon binding assays. The notation “N/A” was used for binding curves that either contained data points or error bars that fell below the x-axis. All errors are reported as standard error of the mean.

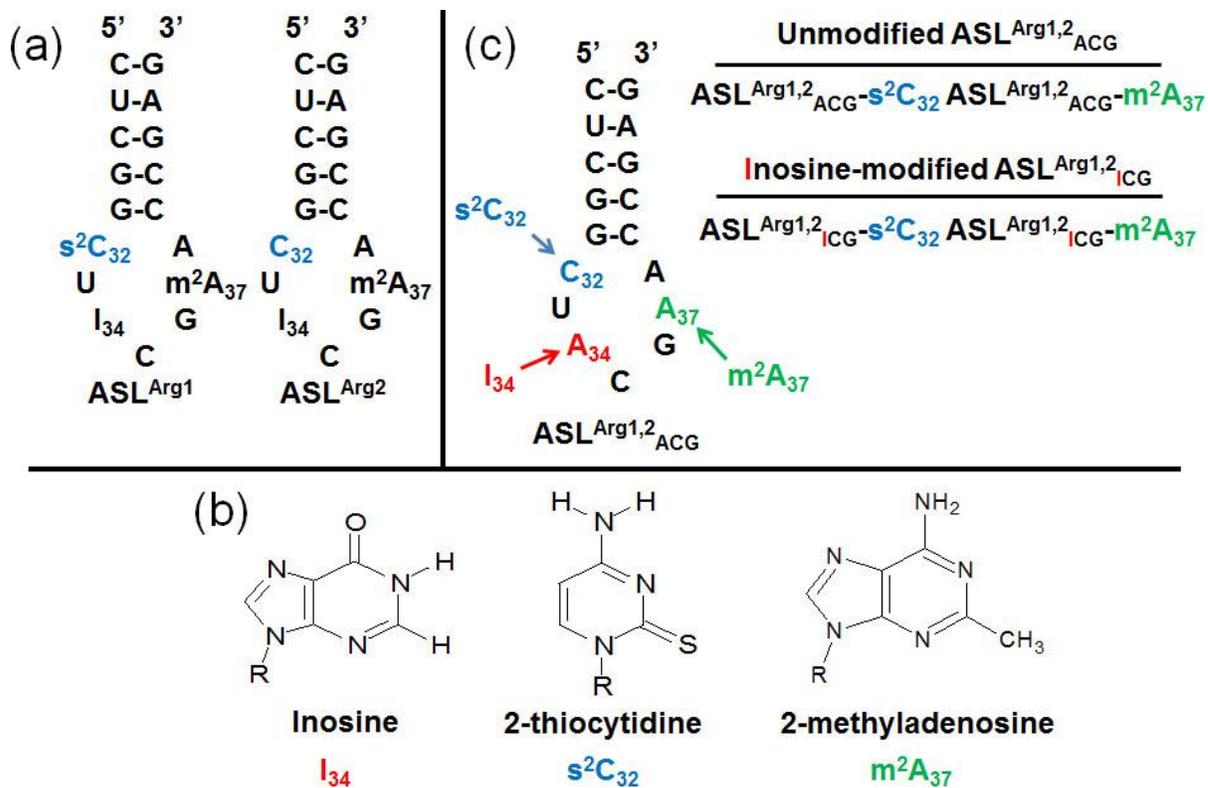

Figure 1. Anticodon stem and loop domains of *E. coli* tRNA^{Arg} (ASL^{Arg1,2}) and their modified nucleosides. (a) The primary sequence and secondary structures of the ASLs of the *E. coli* tRNA^{Arg1} and tRNA^{Arg2} with the difference between the two isoacceptors noted as a blue s²C residue at position 32 of ASL^{Arg1}. (b) The chemical structures of the three naturally occurring modified nucleosides, inosine (I₃₄), 2-thiocytidine (s²C₃₂) and 2-methyladenosine (m²A₃₇). (c) Primary sequence and secondary structure of the ASL^{Arg1,2} showing the sites of modification that resulted in the variously modified six ASLs used in this study.

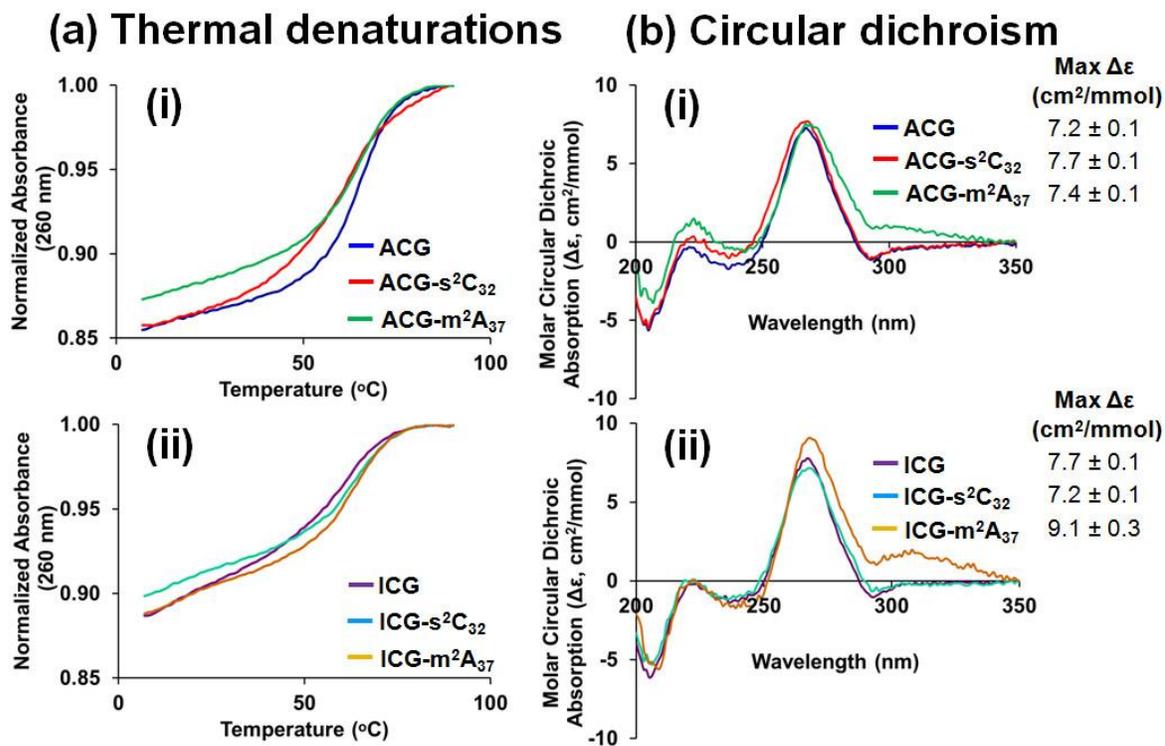

Figure 2. Thermal stability and base stacking of the ASL^{Arg1,2} constructs. (a) UV-monitored thermal denaturation and renaturation spectra of the ASL (~0.2 OD₂₆₀). Absorbance data was collected at 260 nm. The profiles shown are averages of at least five repeated denaturation/renaturation cycles (7-92 °C; 1 °C /min) of (i): ASLs containing A₃₄ and (ii): ASLs containing I₃₄. (b) Circular dichroism (CD) spectra of all six ASL constructs. Spectra are the averages of nine normalized molar circular dichroic absorption spectra collected during three independent experiments with data points collected at a resolution of 1 nm for (i): ASLs containing A₃₄ and (ii): ASLs containing I₃₄. Errors for maximum ellipticity are reported as one standard deviation from the mean.

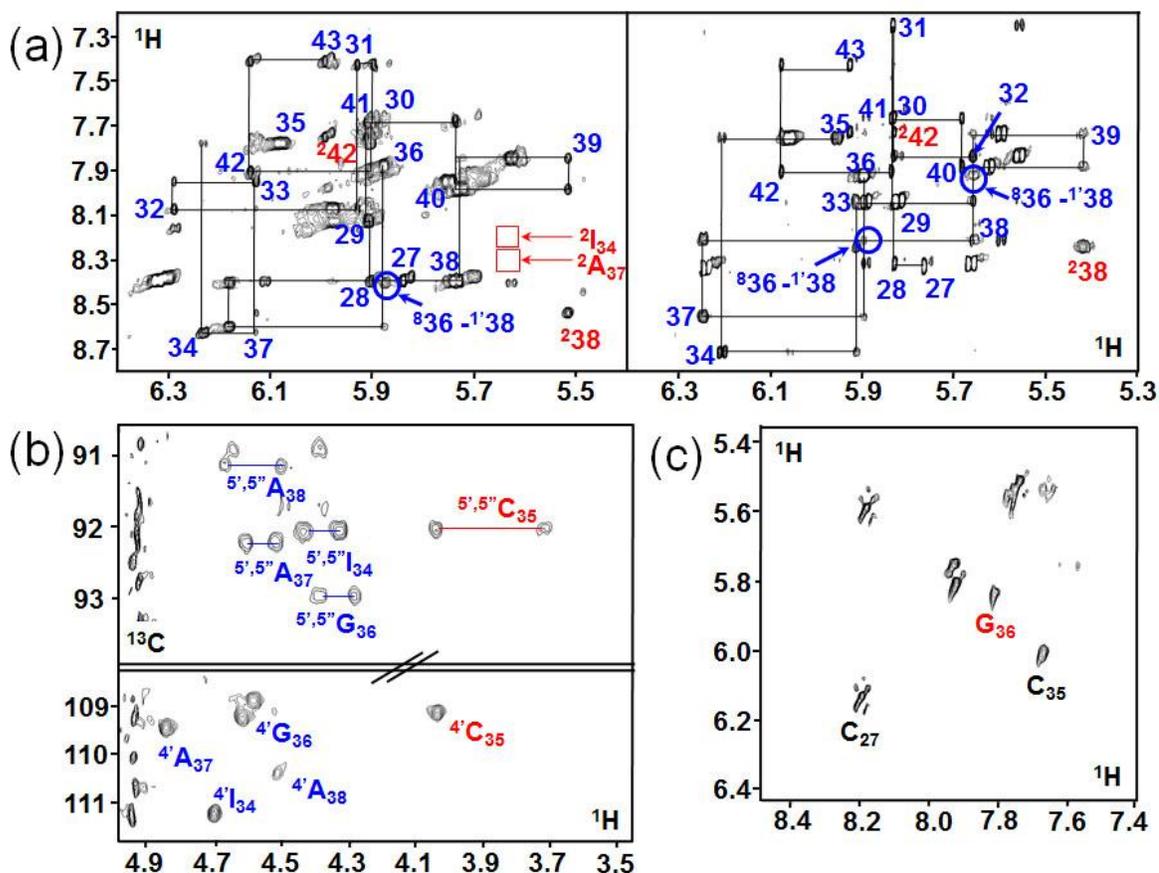

Figure 3. NOE-‘walk’ of NMR spectra indicate that ASL^{Arg1,2}ICG forms a A-form helix. (a) The sequential H1’-aromatic connectivities of the NOESY spectra. The H1’ and H5 to aromatic region of a NOESY spectra (25 °C; mixing time of 400 ms; D₂O) are shown for **Left:** ASL^{Arg1,2}ICG-s²C₃₂; and **Right:** ASL^{Arg1,2}ICG. The unusual NOE connectivities between G₃₆ H8 – A₃₈ H1’ and A₃₈ H8 – G₃₆ H1’ are indicated. The lack of H2 resonances for I₃₄ and A₃₇ are denoted by red arrows and boxes showing where they would be expected. (b) A part of the ¹H-¹³C HSQC spectrum of ASL^{Arg1,2}ICG shows the unusual upfield chemical shift of the C₃₅H₄’, H₅’ and H₅’’ resonances. (c) NOESY spectrum of ASL^{Arg1,2}ICG (50 ms) The H1’ and H5 to aromatic region of a NOESY spectrum (25 °C; mixing time 50 ms; D₂O). The nucleoside numbering scheme reflects the numbering used in Figure 1.

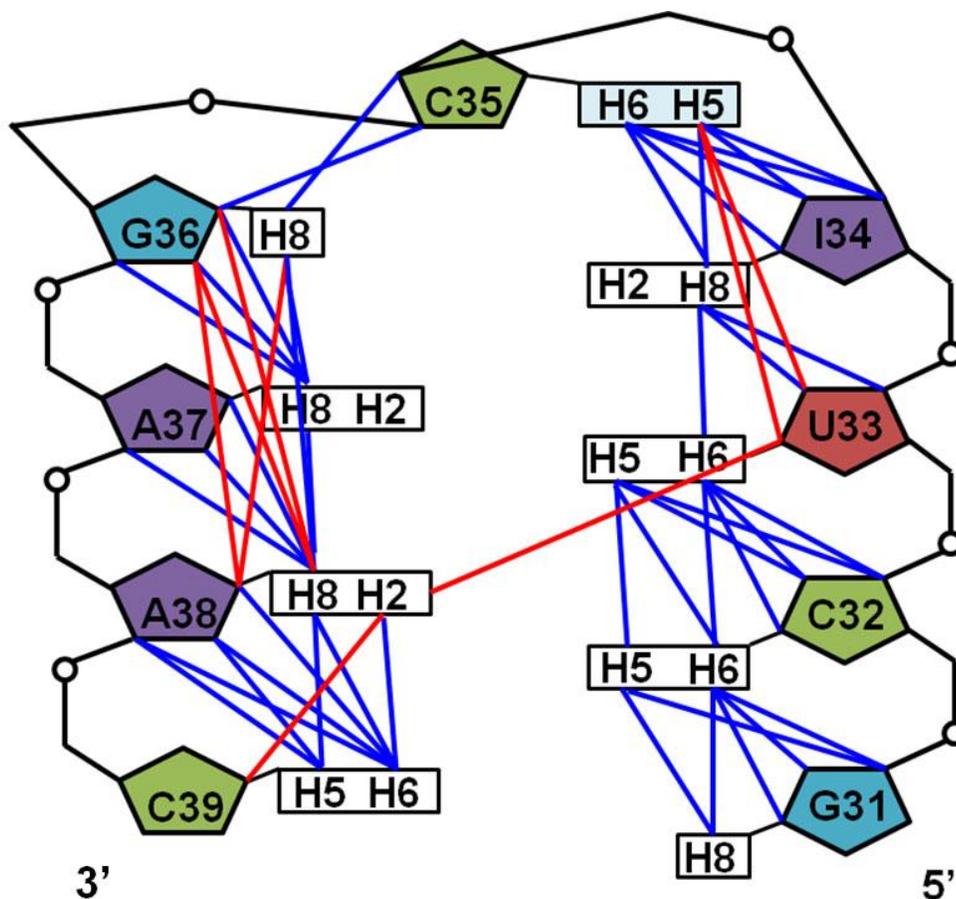

Figure 4. Inter-nucleotides NOEs of ASL^{Arg1,2}_{ICG}. A considerable number of NOEs were observed for the loop nucleosides C₃₁ to A₃₉ of all of the ASL^{Arg1,2}. The diagram illustrates some of the NOE observed for the anticodon loop nucleosides of ASL^{Arg1,2}_{ICG}. In blue and red are the sequential ($i \rightarrow i+1$) and non-sequential inter-nucleotides NOEs, respectively.

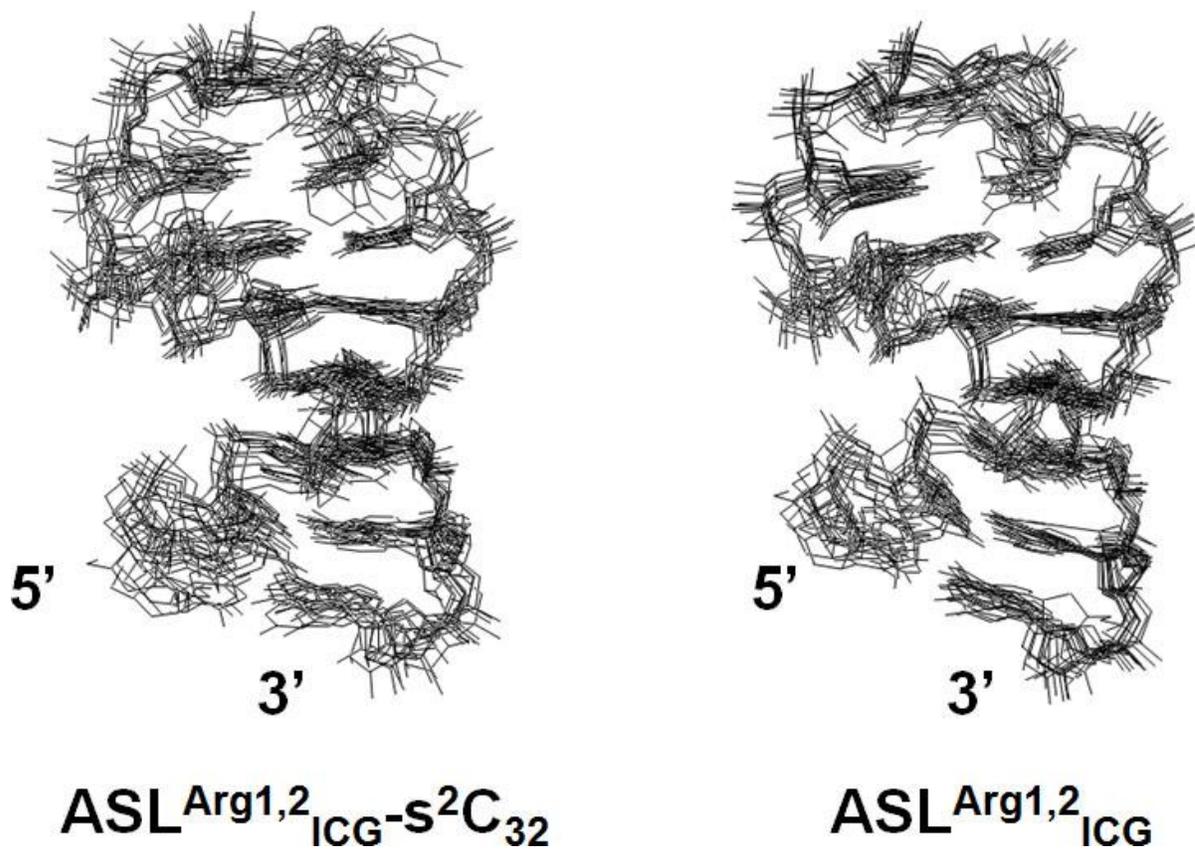

Figure 5. Lowest energy structures derived from NMR. Superposition of the 10 lowest energy structures of $ASL^{Arg1,2}_{ICG}$ (right) and $ASL^{Arg1,2}_{ICG-s^2C_{32}}$ (left). For superposition, the individual structures are fitted to the average structure for nucleosides s^2C_{32}/C_{32} to A_{38} (hydrogen atoms have been removed for clarity).

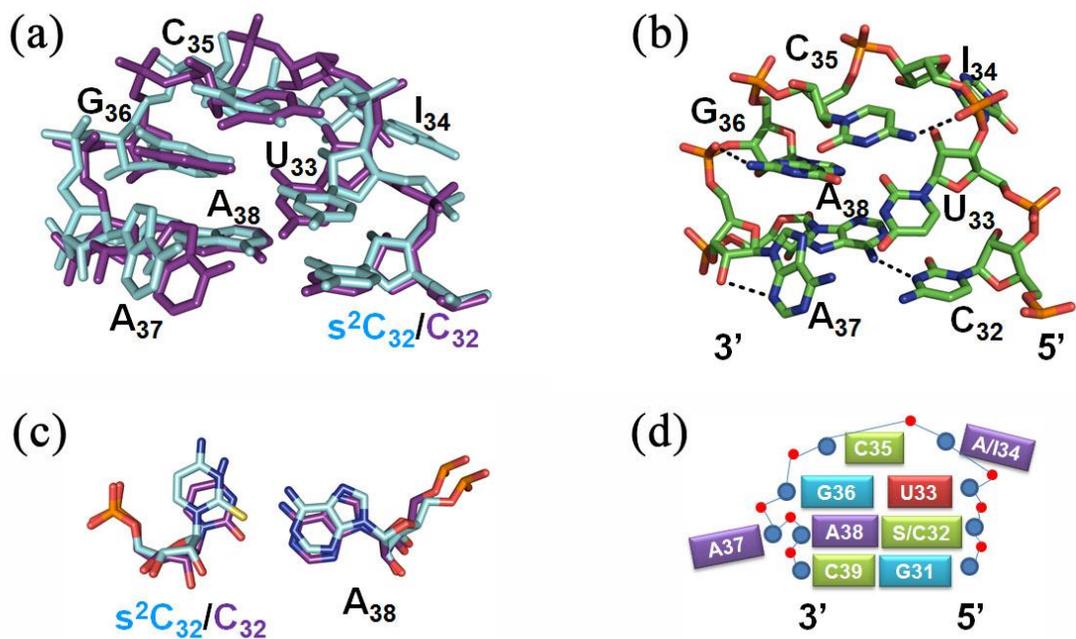

Figure 6. Structure and base pairing across the ASL^{Arg1,2}_{ICG} loop; comparison of the ASL^{Arg1,2}_{ICG} and ASL^{Arg1,2}_{ICG-s²C₃₂} loop conformations (nucleoside 32 to 38). (a) Superposition of the average structures for the nucleosides s²C₃₂/C₃₂ to A₃₈ of ASL^{Arg1,2}_{ICG} (violet) and ASL^{Arg1,2}_{ICG-s²C₃₂} (cyan). (b) The intra-loop hydrogen bond pattern stabilizing the ASL^{Arg1,2}_{ICG} loop conformation (black dashes). (c) The s²C₃₂/C₃₂•A₃₈ base pairs in ASL^{Arg1,2}_{ICG} and ASL^{Arg1,2}_{ICG-s²C₃₂}. (d) Schematic representation of the general conformations adopted by ASL^{Arg1,2}_{ICG} and ASL^{Arg1,2}_{ICG-s²C₃₂}. For clarity, the hydrogen atoms have been removed in all structures.

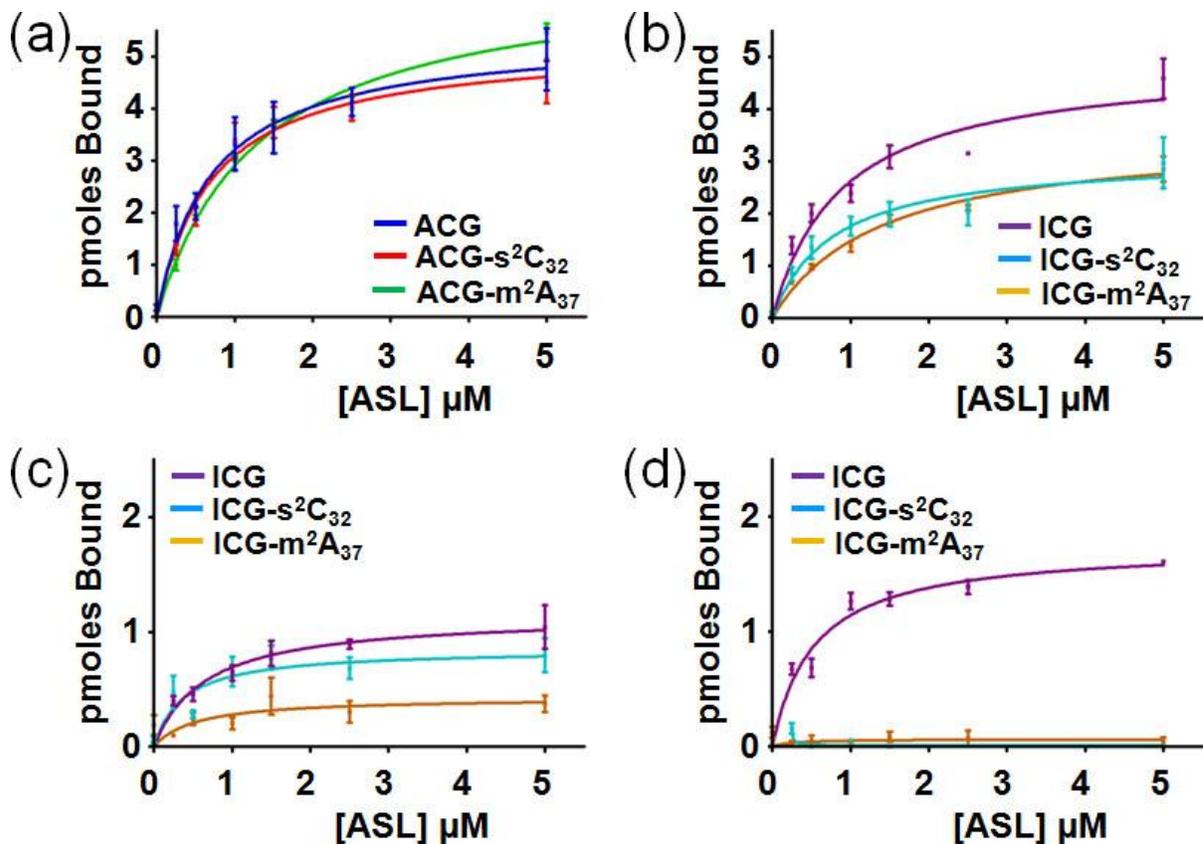

Figure 7. A-site codon binding by variously modified ASL^{Arg1,2}. The abilities of the various ASL^{Arg1,2} to bind A-site codons was assessed: **(a)** A₃₄-containing ASLs, ASL^{Arg1,2}_{ACG}, ASL^{Arg1,2}_{ACG-s²C₃₂} and ASL^{Arg1,2}_{ACG-m²A₃₇}, bound to CGU; **(b)** I₃₄-containing ASLs, ASL^{Arg1,2}_{ICG}, ASL^{Arg1,2}_{ICG-s²C₃₂} and ASL^{Arg1,2}_{ICG-m²A₃₇} bound to CGU; **(c)** I₃₄-containing ASLs, ASL^{Arg1,2}_{ICG}, ASL^{Arg1,2}_{ICG-s²C₃₂} and ASL^{Arg1,2}_{ICG-m²A₃₇}, bound to CGC; and **(d)** I₃₄-containing ASLs, ASL^{Arg1,2}_{ICG}, ASL^{Arg1,2}_{ICG-s²C₃₂} and ASL^{Arg1,2}_{ICG-m²A₃₇}, bound to CGA. Data for the binding of ASL^{Arg1,2}_{ACG-s²C₃₄} and ASL^{Arg1,2}_{ACG-m²C₃₇} to the non-cognate, synonymous codons CGC and CGA and the corresponding error bars fell below the x-axis and were excluded from the figure. Dissociation constants (K_d) were calculated for those ASL^{Arg1,2} constructs and codons for which there was observable binding to their synonymous codons (Table 2).

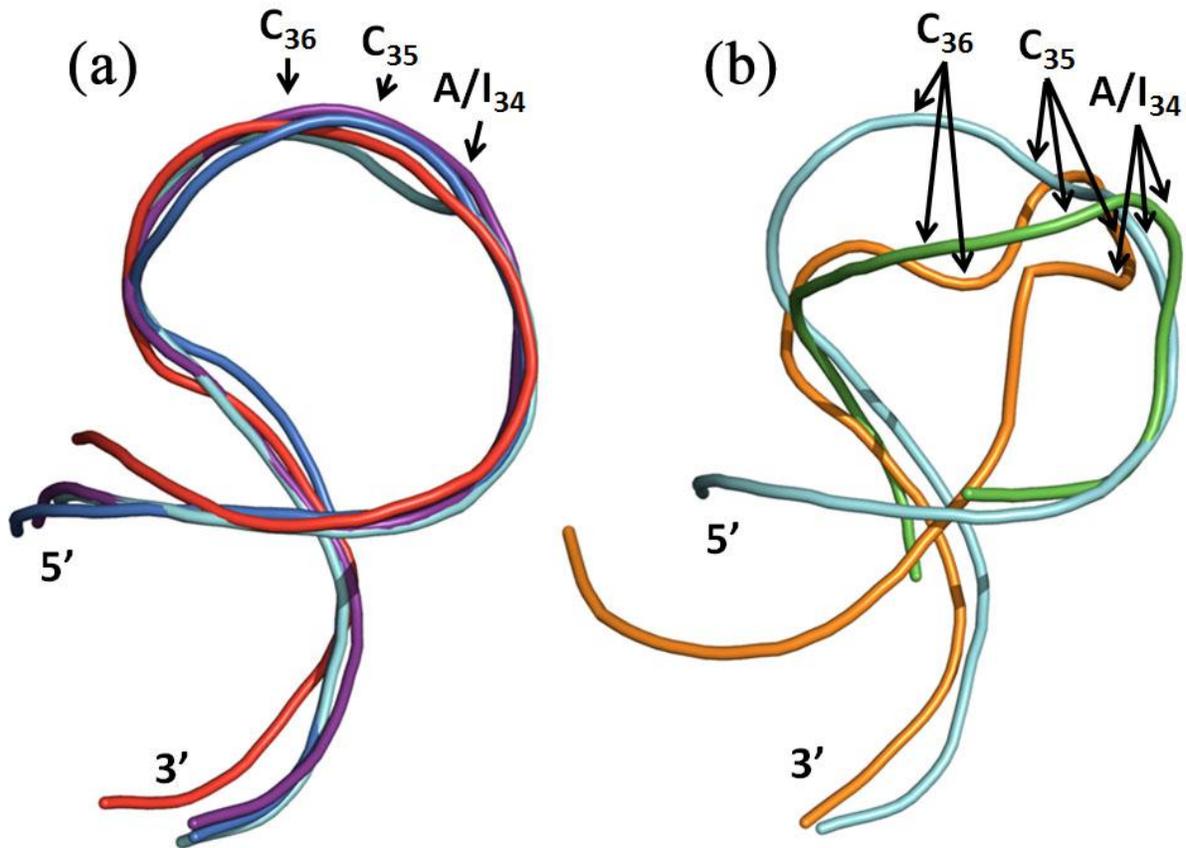

Figure 8. Solution and crystal structures of the arginyl-tRNA synthetase, and ribosome bound ASL^{Arg1,2} are very different from each other. (a) A superimposition of ASL^{Arg1,2}_{ACG} (red), ASL^{Arg1,2}_{ACG-s²C₃₂} (blue), ASL^{Arg1,2}_{ICG} (violet) and ASL^{Arg1,2}_{ICG-s²C₃₂} (cyan) reveals only minor differences in the solution structures of each respective ASL. (b) A superimposition of ASL^{Arg1,2}_{ICG-s²C₃₂} (cyan), ASL^{Arg1,2}_{ICG} bound to the ribosomal A-site (green) and yeast ASL^{Arg1,2}_{ICG} bound to the arginyl-tRNA synthetase shows drastic conformational differences among the three structures. The nucleosides were removed for clarity, and the positions of the backbone phosphates of the anticodon are shown.

William A. Cantara, Erick Harr and Paul F. Agris

3.1 Statement of project contribution

The objective of this project was to determine if there were specific conformational pathways leading from the solution structure of the ASL^{Arg1} to that of the ASL on the cognate aminoacyl-tRNA synthetase, and to that on the programmed ribosome. I had the pleasure of training a very helpful undergraduate, Erick Harr, to assist with the preparation and simulation of the ribosome-bound structures as well as analysis and interpretation of the resulting structural and statistical data. I was responsible for all aspects of this project, from initial strategy to data interpretation, as well as delegation to Erick and coordination with the personnel from the Research Information Technology department.

Abbreviations: ASL, anticodon stem and loop; I₃₄, inosine in position 34; mRNA, messenger RNA; RMSD, root mean square deviation; s²C₃₂, 2-thiocyridine in position 32; m²A₃₇, 2-methyladenosine in position 37; MD, molecular dynamics; TMD, targeted molecular dynamics.

Keywords: 2-thiocyridine, inosine, 2-methyladenosine, RNA structure, RNA function, molecular dynamics

3.2 Abstract

Anticodon stem and loop domain (ASL) modifications in tRNA affect the conformation and dynamics of the structure at equilibrium, thus modulating the decoding function of the tRNA. It has been shown that the modifications 2-thiocytidine at position 32 (s^2C_{32}) and 2-methyladenosine at position 37 (m^2A_{37}) of *Escherichia coli* (*E. coli*) ASL^{Arg1,2}_{ICG} can alter decoding capacity, while having no effect on the solution structure at equilibrium. Spectroscopic results suggest that modifications modulate the thermal stability and base stacking properties of the ASL. Additionally, this ASL has the uncommon property of adopting very different structures in solution, when bound to the cognate aminoacyl-tRNA synthetase and on the ribosome. It is unclear how modifications modulate decoding ability without altering the structure at equilibrium and whether they play a role in regulating adoption of the very different, but necessary conformations for aminoacylation and ribosome-mediated codon binding. To test whether modifications alter the conformational space of ASL^{Arg1,2}_{ICG}, explicit solvent all-atom molecular dynamics (MD) simulations were performed on the ASL in different states of modification using the three different conformations as starting conditions. These MD results show that modifications influence conformational dynamics in a manner that is dependent both on the state of modification and the starting conformation, suggesting that modifications alter the ability of the ASL to switch conformations. In order to investigate the pathways of the energy landscape between the different conformations, all-atom targeted MD (TMD) simulations were conducted. Preliminary investigations of the preferred conformational pathways between the solution structure and the canonical U-turn motif using TMD indicate that at least five different pathways are used by ASL^{Arg1}. The distribution of which pathways each ASL construct used was dependent on modification state. Therefore, modifications altered the residue-specific conformational space of the ASL, directing passage through certain conformational pathways and intermediates.

3.3 Introduction

Proper translation of the genetic code is highly dependent on nucleoside modifications of tRNA's anticodon domain [1,2]. There are no less than 93 different modifications that can be found in tRNAs of all species [3]. These modifications are highly enriched within the anticodon stem and loop (ASL) in both number and diversity [4,5]. ASL modifications perform many crucial translational functions such as reading frame maintenance [6,7] and promoting translocation [8]. Additionally, modifications play a critical role in pre-structuring the loop into a U-turn-like conformation common among ASLs [1,2,9-11]. The pre-structuring is important to reduce the amount of ASL deformation necessary to adopt the canonical U-turn motif that is required for the binding of codons in the ribosomal A-site. This, in turn, reduces the requisite energy for proper codon recognition as the tRNA is used repeatedly.

In *Escherichia coli*, tRNA^{Arg1}_{ICG} (Figure 1a) is responsible for decoding three of the six arginine codons. These include the two common codons CGU and CGC in addition to the rare CGA codon [12]. Interestingly, another isoacceptor, tRNA^{Arg2}_{ICG}, is also thought to be responsible for decoding these same codons. The two isoacceptors have nearly identical primary structure, differing only at position 20, where tRNA^{Arg2}_{ICG} contains an additional adenosine in the dihydrouridine loop, and at position 32 (see Figure 1a for nucleoside numbering) in the anticodon stem and loop (ASL) where tRNA^{Arg1}_{ICG} has the rare cytidine modification 2-thiocytidine (s^2C_{32}) [13-15]. In addition to the rare s^2C_{32} modification in tRNA^{Arg1}_{ICG}, both isoacceptors contain adenosine modifications at positions 34 and 37, inosine (I₃₄) and 2-methyladenosine (m^2A_{37}), respectively (Figure 1b). Inosine has the functional property of allowing the tRNA to decode three different codons ending in U, C or A when located at position 34, the “wobble” position [16].

The rare s^2C_{32} modification is of particular interest because of both its rarity and the fact that it is found in four out of five of the *E. coli* arginyl tRNA isoacceptors and tRNA^{Ser2}_{GCU} [13]. However, relatively little is known about the 2-thiolated cytidine in the context of

structure and function of the ASL. Indeed, the only arginine isoacceptor lacking s^2C_{32} is tRNA^{Arg2}_{ICG}, which has an otherwise identical ASL sequence as tRNA^{Arg1}_{ICG} [13-15]. The identity and geometric orientation of the residue at position 32 has been shown to regulate the ability of the tRNA to discriminate between different codons [17]. Position 32 is modified in ~32% of known tRNA sequences, 83% of which are in the form of either 2-thiocytidine or a 2'-*O*-methylated pyrimidine [13]. These types of modifications have similar structural characteristics. The 2'-*O*-methyl group causes a steric hinderance with the aromatic base of the nucleoside in the C2'-*endo* sugar pucker conformation, resulting in the energetically more favorable C3'-*endo* conformation [18-20]. The larger atomic radius of the thioketone in 2-thiolated pyrimidines as compared to that of the 2-carbonyl stabilizes both a C3'-*endo* sugar pucker and an *anti* *N*-glycosidic orientation. The greater polarizability of the thioketone promotes stacking interactions between adjacent nucleosides [21]. There are three crystal structures containing the singly modified version ASL^{Arg1}_{ICG} with only inosine at position 34. One contains the entire tRNA bound to the yeast arginyl-tRNA synthetase (argRS) [22]. The two other crystal structures show the ASL bound to non-cognate, synonymous codons in the ribosomal A-site, one bound to CGC and one bound to CGA [23]. Although the crystal structure of the tRNA^{Arg1}_{ICG}-argRS complex is from yeast [22], a crystal structure of the bacterial synthetase from *Thermus thermophilus* [24] shows a high amount of structural conservation when compared to the argRS (heavy atom RMSD difference of 2.73Å, Figure 2a). Additionally, the yeast anticodon loop primary sequence is identical to that of *E.coli* and other bacteria [13]. Therefore, it is likely that the ASL must adopt a very similar conformation in bacteria.

Surprisingly, the conformations of ASL^{Arg1}_{ICG} when bound to the ribosome and argRS are drastically different (Figure 2b). When bound in the ribosomal A-site, ASL^{Arg1}_{ICG} conforms to the canonical U-turn structure in which all loop residues are in the C3'-*endo* sugar pucker. There is highly organized base stacking on both the 5' and 3' sides of the loop. The Watson-Crick faces of the anticodon residues are solvent exposed [23]. In contrast to this conventional structure, ASL^{Arg1}_{ICG} bound to argRS reveals a highly distorted loop. C₃₅, G₃₆

and A₃₈ are flipped outside of the loop, and G₃₆ and A₃₈ are buried in the protein. I₃₄ forms a stacking interaction with tryptophan-567 [22]. The structure is stabilized by a cross-strand stacking interaction of A₃₇ between the terminal stem base pair and C₃₂. This distortion of the ASL may reflect the specificity of synthetase recognition. With little room for alteration in the position 35 and 36 anticodon residues, these structures appear to hinge on the chemical properties of the nucleosides at positions 32, 37 and 38.

We recently reported the structural, thermodynamic and functional implications of the three tRNA^{Arg1}_{ICG} modifications in the context of the ASL [25]. The study was, however, limited by the inability to obtain the triply modified ASL for experimentation and was therefore carried out using six differentially modified ASLs. While the ASLs showed significant differences in their thermodynamic properties and codon binding capabilities, their solution structures were nearly identical. Specifically, the modifications on the 5' side of the loop, s²C₃₂ and I₃₄, caused a destabilization of the ASL and the 3' modification, m²A₃₇, tended to have a stabilizing effect. Functionally, I₃₄, as predicted by the “Wobble Hypothesis” [16], enabled decoding of all three synonymous codons (CGU, CGC and CGA). In combination with I₃₄, however, both s²C₃₂ and m²A₃₇ restricted codon recognition to only CGU and CGC. These thermodynamic and functional differences were not evident in the solution structures of the ASLs. All differentially modified ASLs conformed to a very stable pseudo 5'UNCG^{3'} tetraloop conformation. Interestingly, this structure does not present any of the hallmark characteristics of either of the crystal structure conformations seen on the ribosome or argRS (Figure 2b).

In the present study, molecular dynamics simulations were conducted to decipher the conformational energetic and energy landscape by which anticodon domain modifications of tRNA^{Arg1}_{ICG} modulate thermodynamic and functional decoding characteristics. Additionally, we sought to predict whether the fully modified ASL (ASL^{Arg1}_{ICG}-s²C₃₂;m²A₃₇) would promote the necessary conformational transitions to enable three-fold degenerate codon recognition. Seven ASLs with different states of modification (Figure 1a) were simulated from the three known starting structures (solution, ribosome-bound and argRS-bound, Figure

2b) using standard explicit solvent molecular dynamics. Then, targeted molecular dynamics were conducted to simulate the transition from the solution structure to a canonical U-turn conformation. Here, we report that modifications can both modulate residue-specific dynamics and alter the pathways for the lowest energy transition between two biologically important conformations. The results support the hypothesis that modifications act as regulators of aminoacylation and ribosome-mediated decoding by modulating the energy requirement for adopting the necessary conformations for each activity.

3.4 Results

3.4.1 *ASL and individual residue flexibility*

The results of biophysical characterizations have shown modification-induced biophysical variation in differentially modified ASL^{Arg1}_{ICG} constructs [25]. To further investigate the molecular mechanisms underlying these variations, standard explicit solvent molecular dynamics simulations were performed using the SANDER module in the AMBER 11 suite of programs [26]. Explicit solvent simulations are performed with actual atomistic simulations of water molecules in potential box surrounding the solute. This type of simulation was chosen based on the inherent properties of water molecule stabilization of coordinated ions and RNA:RNA interactions such as base stacking and base pairing. Starting structures were derived from NMR solution structures previously solved [25], minimized, equilibrated and simulated at constant temperature and pressure for 6 ns. The final 5 ns of production simulation trajectories were analyzed using the ptraj module from AmberTools1.5 [26]. A plot of heavy atom root mean square deviation (RMSD) *versus* time reveals only slight variations between the differentially modified ASLs (Figure 3a). In fact, none of the plots show any significant deviation from what would be considered the average structure RMSD.

To more specifically determine the effects of modifications, B-factors (a measure of atomic fluctuation in which a higher value corresponds more conformational variability)

were calculated from the trajectories for each residue. For ASLs that contain both A₃₄ and I₃₄ the flexibility of the stem residues C₂₇-G₃₁ and C₃₉-G₄₃ was significantly less than that of the loop residues, with the exception of the terminal stem residues (Figure 3b). This is expected due to the lower stability of terminal base pairs and the high stability of internal base pairs in A-form RNA stems. Interestingly, the flexibility of residues C/s²C₃₂ and U₃₃ were significantly less flexible than the other stem residues. Since the key differences in decoding were seen for the inosine-containing ASLs [25], it is interesting to note the properties of modifications in these ASLs. First, m²A₃₇ caused a significant increase in its own conformational space; but had little effect on any other residue. In contrast to m²A₃₇, s²C₃₂ caused a slight increase in the flexibility of all three anticodon residues and contributed a significant decrease in plasticity of A₃₇. Though empirical studies on the fully modified ASL were precluded by difficult chemical synthesis, the molecular dynamics-derived B-factors predicted that this ASL would have loop deformability properties that closely resemble that of the singly modified ASL^{Arg1}_{ICG} with one exception. Residues C₃₅ and G₃₆ would have slightly more conformational space. In summary, molecular dynamics simulations reveal trends in loop residue flexibility that may affect the ability of the ASL to adopt different induced conformations when bound to the ribosome or argRS.

While modification-induced changes in conformational space of the ASL solution structure ASL were evident, these results could not be extrapolated to that of the loop residues bound to codons in the ribosome or those of the argRS-bound conformation. Therefore, the differentially modified ASLs were simulated using both their ribosome-bound and argRS-bound structures in the absence of the bound ribosome and argRS. The same simulation conditions were applied as with the solution structure. This allowed for a macromolecule-independent determination of the relative stability and flexibility of each ASL conformation. Similar to the NMR solution structure, the RMSD vs time plots of the differentially modified ASLs in either starting conformation were very similar (Supplementary Figure S1). B-factors for each individual residue were calculated. In both the canonical U-turn conformation seen in the ribosomal A-site (Figure 4a) and the highly

distorted argRS-bound conformation (Figure 4b), the stem residues were very stable and show very little flexibility with the exception of the terminal stem residues. When in the U-turn conformation of the ribosome structure, there is a slight increase in the B-factors associated with the anticodon residues over that seen for the solution structure (Figure 4a). This is not surprising considering the highly stable interactions occurring between the loop residues and the flared-out nature of A₃₇ in the UNCG motif of the solution structure and the solvent-exposed positioning of the anticodon residues in the U-turn. Similar to the U-turn conformation, the distorted conformation of the argRS-bound ASLs allowed for a significant increase in the B-factors associated with U₃₃, A/I₃₄ and C₃₅ (Figure 4b). In both the argRS and ribosome structures, A₃₇ showed a much more stable dynamic than in the solution structure.

In addition to a dependence on starting structure, the residue-specific dynamics were also dependent on modification state. When modified with m²A₃₇, this residue in the solution structure is significantly more flexible as indicated by a higher B-factor; however, this effect is more or less pronounced in the presence of I₃₄ or s²C₃₂, respectively (Figure 3b). Despite the ability to stabilize position 37, s²C₃₂ in combination with I₃₄ enhances the motion U₃₃, I₃₄, C₃₅ and G₃₆. With the exception of the fully modified ASL, modifications generally have a stabilizing effect on all loop residues of the U-turn structure seen on the ribosome, compared to the unmodified ASL (Figure 4a). In contrast, modifications appear to destabilize the loop residues of the argRS-bound conformation.

3.4.2 Conformational pathways between UNCG and U-turn motifs

While standard molecular dynamics simulations showed that modifications can modulate loop plasticity and deformability, using only standard molecular dynamics, it is impossible to determine whether the modifications can regulate the ability of the ASL to conform to a canonical U-turn structure. A comprehensive study of all ASL constructs is currently in progress; however, complete targeted molecular dynamics (TMD) simulations were performed on unmodified ASL^{Arg1}_{ACG} and s²C₃₂, I₃₄ and m²A₃₇ modified ASL^{Arg1}. This was

used to investigate the conformational pathways that are traversed between the solution structure and the U-turn necessary for A-site codon binding. This strategy introduced an energy penalty to the simulation that is proportional to the heavy atom RMSD between the current structure and a reference structure, in this case, the reference structure is the U-turn conformation. This energy penalty creates a bias in which the system tends toward the reference structure.

During TMD simulations, five different conformational pathways were observed for the unmodified and various singly modified ASLs (Table 1, Figure 5 and 6). The most unusual pathway, Pathway 2, only occurred during simulations involving the unmodified ASL. It is characterized by an intermediate in which A₃₇ stacks between A₃₈ and C₃₉. This breaks the stacking interaction between A₃₇ and G₃₆, which allows G₃₆ the flexibility to swing outside of the loop, where the *N*-glycosidic (χ) bond is free to rotate from *syn* to *anti*. G₃₆ forms a highly stable stacking network with C₃₅ and A₃₄, which flip out to stack with G₃₆. Finally, A₃₇ was released from base-pairing with C₃₂ and stacking between A₃₈ and C₃₉ to flip out and complete the highly stacked network from A₃₄ to C₃₉. This allowed A₃₈ to re-form a non-canonical base pair with C₃₂. In contrast to Pathway 2, Pathways 1, 3, 4 and 5 are characterized by an initial structural change in which G₃₆ and A₃₇ flip from the inside to the outside of the loop at the same time and stack together. During this flip, the χ dihedral angle of G₃₆ either switches from *syn* to *anti* or stays *syn* for Pathways 1 and 3 or Pathways 4 and 5, respectively. In all four of these pathways, C₃₅ then flips from the inside to the outside of the loop creating the characteristic U-turn with a highly stacked network of bases from the anticodon along the 3' side of the loop. In Pathway 4, it is now that the base of G₃₆ rotates from *syn* to *anti*-conformation; however in Pathways 3, 4 and 5, C₃₅ is not able to adopt an *anti*-conformation for the duration of the simulation.

Based on five repetitions for each ASL construct, we have divided the pathways of each ASL into a percentage chance of following each pathway (Table 2). Interestingly, only unmodified ACG was able to follow Pathway 2. Indeed, either of the modifications individually was able to completely abrogate the ability of A₃₇ to stack between A₃₈ and C₃₉

and form a non-canonical base pair with C₃₂. Despite an apparent preference for Pathway 2, ACG also followed Pathway 1 in 40% of the simulations. Both of these pathways resulted in the unmodified ASL adopting a canonical U-turn conformation with all loop bases in the *anti* glycosidic conformation. Similarly, the addition of m²A₃₇ still allowed for Pathway 1 to be followed 40% of the time, however, 60% of the time, Pathways 3, 4 and 5 were used resulting in either one or both of C₃₅ or G₃₆ adopting an unconventional *syn* conformation. For the remaining two singly modified ASLs with s²C₃₂ and I₃₄, TMD simulations revealed that all replicates followed Pathways 3, 4 or 5 indicating that there was a preference for at least one of the anticodon residues to be in the *syn* *N*-glycosidic conformation. To summarize the results of the TMD simulations, each differentially modified ASL was able to follow anywhere from two to four different conformational pathways from solution structure to ribosomal A-site structure. The distribution of pathways followed was dependent upon modification state. The modification-dependent pathways followed by either the unmodified ACG or singly modified ASL^{Arg1}_{ACG-m²A₃₇} appear to be preferential due to their ability to adopt the fully canonical U-turn conformation. One commonality of all pathways is the preference for the C2'-*endo* sugar conformation of G₃₆ until it rotates outside of the loop. It then adopts a C3'-*endo* conformation independent of the *N*-glycosidic rotation.

3.5 Discussion

The structure and function relationship of the anticodon domain of *E.coli* tRNA^{Arg1}_{ICG} is an anomaly in the field of tRNA modification research. First, this isoacceptor is solely responsible for decoding both very common codons (CGU and CGC) and a very rare codon (CGA) [12,25]. Secondly, the structure of the ASL has been shown to be independent of up to two modifications [25]. Finally, the singular structure seen in solution for all differentially modified ASLs is more similar to highly stable 5'-UNCG-3' motif [25] rather than either the canonical U-turn conformation required for codon binding in the ribosomal A-site [23] or the highly distorted structure required for argRS recognition [22]. To investigate these unusual

characteristics and test the hypothesis that modifications alter the dynamic properties of these ASLs, molecular dynamics simulations were performed. Here, we have shown both how modifications can modulate the deformability of the loop by specifically altering the flexibility of specific loop residues and that modifications can alter the conformational pathway between the solution structure and the U-turn motif.

Each of the three conformations adopted by the singly modified ASL^{Arg1}_{ICG} has different identifying structural characteristics. In the UNCG-like motif, there is a stable stacking interaction between G₃₆ and A₃₈ which both stabilizes G₃₆ in a *syn N-glycosidic*, C2'-*endo* orientation and causes A₃₇ to be flipped out of the loop and become fully solvent exposed [25]. Further stabilizing G₃₆ in this unfavorable geometry is a single hydrogen bond between G₃₆N2 and the phosphate of A₃₇. This unusual positioning of G₃₆ and the consequent stacking with C₃₅ results in the stabilization of an unusual positioning of C₃₅, directly below the base of U₃₃. Indeed C₃₅ is also stabilized by a hydrogen bond between C₃₅N4 and the backbone phosphate of A/I₃₄. It should be noted that in this conformation, C/s²C₃₂ stacks well between G₃₁ and U₃₃ and makes an unusual bifurcated hydrogen bond with A₃₈.

In contrast to the UNCG motif, the U-turn is a highly ordered structure on the ribosome [23]. All of the loop residues are very well stacked and adopt a C3'-*endo* sugar pucker and *syn* glycosidic rotation. This structure is also closed by a non-canonical base pair between C₃₂ and A₃₈; however, in a slightly different geometry than that seen in the UNCG motif. Contrast this highly ordered U-turn structure with the disordered conformation of the ASL when bound to argRS. The argRS-bound conformation reveals that the strongest identity determinant, C₃₅, is positioned outside of the loop where it stacks with tryptophan 569 of the protein. It is coordinated in this position by two hydrogen bonds with the backbone atoms of histidine 22 and 23. Also, A₃₈ is exposed and is buried within the protein, resulting in C₃₂ forming a cross-loop stack with A₃₇.

3.5.1 Modifications modulate loop flexibility

There is a common trend with ASL modifications wherein the ASL tends to be stabilized

and less flexible upon modification [27]. This function is not surprising considering a pre-structured and highly stabilized U-turn conformation is beneficial to codon binding by reducing the amount of induced-fit required prior to codon binding [10]. A logical inference can be made for situations in which the ASL is not pre-structured by modifications. In these cases, it should be beneficial for the ASL to be more flexible to reduce the energy required for deforming the loop to adopt a canonical U-turn conformation. However, the preference for flexibility of the ASL will be dependent on the conformation that the ASL is currently adopting. For instance, while ASL^{Arg1}_{ICG} is in the UNCG motif, a higher plasticity for certain residues would be more beneficial to decoding, because of the need for the loop to deform during a conformational transition to the U-turn motif.

Due to significant stabilization of the loop residues while in the UNCG conformation caused by extensive intraloop hydrogen bonding [25], most of the loop residues showed very low B-factors with the exception of the solvent exposed A₃₇ (Figure 3b). When either s²C₃₂ or m²A₃₇ were present without I₃₄, neither modification caused a significant alteration in the motional dynamics of the loop. There was a slight trend in which m²A₃₇ increased its own flexibility and s²C₃₂ reduced the stability of the terminal base pair in the presence of either A₃₄ or I₃₄. The 2-thio modification also has a general property of stabilizing the residue at position 37 which is more pronounced in the presence of I₃₄. While it is unclear how the s²C₃₂ modification destabilizes the terminal base pair or stabilizes position 37, this corroborates thermal melting data suggesting that s²C₃₂ causes a significant reduction in the melt temperature of the ASL ($\Delta T_m = -4.8^\circ\text{C}$) which is less extreme in the presence of I₃₄ ($\Delta T_m = -3.7^\circ\text{C}$) [25]. The inherent flexibility of m²A/A₃₇ may play a role in altering the conformational pathway between the solution and U-turn structure, implicating both s²C₃₂ and m²A₃₇ as modulators of conformational transitions.

The very stable base stacking network of the canonical U-turn motif is responsible for very low B-factors for the loop residues (Figure 4a). Interestingly, a certain amount of conformational change would be expected for the ASL to adopt the correct geometry for each wobble base pair, but not be too flexible that it destabilizes the stacking network of the

anticodon [23]. Certain modification states (unmodified, singly modified with s^2C_{32} and fully modified with s^2C_{32} , I_{34} and m^2A_{37}) showed increased motion at position 34 and, indeed, in the other anticodon residue G_{36} . Also, both the unmodified and fully modified ASLs were more flexible at positions 35 and 37.

The loop residues of the argRS-bound conformation were much more flexible in most positions (Figure 4b). In fact, even the stem residues were slightly more flexible than the solution structure. Also, A_{37} showed much less plasticity than seen in the solution structure. The positioning of A_{37} , stacking across the loop between G_{31} and C_{32} is a characteristic property of the argRS-bound structure [22] and may be important for the ability of the ASL to be induced into this conformation. The much larger amount of flexibility seen in the anticodon residues may be the result of the distorted loop geometry.

3.5.2 Modifications alter intermediates seen during conformational changes

A previous study from our lab described the ability a singly modified ASL^{Arg1} with I_{34} to bind all three synonymous codons (CGU, CGC and CGA) whereas the addition of either s^2C_{32} or m^2A_{37} resulted in negation of binding to the less common CGA codon [25]. It was hypothesized that since the singly modified ASL^{Arg1}_{ICG} adopted a highly canonical U-turn conformation when bound in the ribosomal A-site [23], the deformability of the loop would have a significant impact on the energy required for decoding. A low deformability of the loop, caused by either s^2C_{32} or m^2A_{37} in addition to I_{34} would thus increase the energy of decoding by making the loop residues more rigid. This would explain a lower maximum amount of binding to all codons in the doubly modified state. Additionally, the increased energy barrier inherent to the $I_{34}\bullet A_1$ base pair [28] may be enough to completely abrogate decoding of the rare CGA codon. It was, however, unclear whether modifications would alter how the loop is deformed during an induced fit given that they have no significant effect on the equilibrium solution structure. To investigate whether the modification state of the ASL influences the conformational pathway, targeted molecular dynamics simulations were used to bias the ASL into converting from the solution structure to a canonical U-turn

conformation.

Despite the results of the binding experiments, the simulations suggest that C₃₅ and G₃₆ have difficulty switching from a *syn* to an *anti*-conformation (Table 1). A reduced motion around the χ angle would inhibit the ability of these ASLs to adopt the canonical U-turn structure and, consequently, their ability to bind to codons in the ribosomal A-site. The adoption of a fully canonical U-turn conformation could be completed through interactions within the ribosomal A-site. Therefore, we hypothesize that an interaction with the codon would enable decoding, albeit at a much lower level due to the increased energy of the transition. This hypothesis fits well with the results of binding experiments which suggest that binding to the cognate codon is reduced in I₃₄-containing constructs, perhaps as the result of both a lower base pairing enthalpy and the requirement for additional restructuring of the *N*-glycosidic orientations of two of the anticodon residues. Additionally, this energy requirement leads us to predict that the adoption of a canonical U-turn motif should be slightly less favorable for the doubly modified ASLs. The energy requirement for deformation of the loop in addition to the energy requirement for the purine•purine I₃₄•A₃ base pair [28] would lead to complete abrogation of doubly modified ASL binding to the rare CGA codon.

Many of the differences seen in the intermediates of the different conformational pathways appear to be caused by differences in the initial movements of m²A/A₃₇ relative to the other loop residues. Although only subtle differences are seen in the standard MD-derived B-factors of the loop residues in the solution structure (Figure 3b), correlations are present. In the unmodified construct, which follows Pathway 2 60% of the time, A₃₇ and A₃₈ have less conformational space, suggesting that this state of modification may not allow A₃₇ to easily stack with G₃₆ during the initial stages of the conformational change. Indeed, the allowance for this initial intermediate in the singly modified constructs may cause the ASLs to get trapped in a free energy well, making it more difficult for the anticodon residues to adopt the correct *N*-glycosidic torsion angles. These results predict that methods of stabilizing the *syn* glycosidic rotation seen in the solution structure such as introduction of 6-methylcytidine at

position 35 should inhibit the ability of the ASL to bind to synonymous codons [29]. Similarly, the use of locked nucleic acid chemistry to alter the preference for G₃₆ to either C3'-endo or C2'-endo [30] should alter the preferential conformation of the ASL to either the U-turn or the solution and argRS-bound structures, respectively. For conversion to the canonical U-turn, preference for a C3'-endo conformation should reduce the energy barrier associated with the transition to the outside of the loop, easing the *syn* to *anti* rotation.

It should be noted, however, that the energy penalty introduced to the simulations is not constant. As the target RMSD is reduced linearly with time, the simulation has the ability to get “stuck” in energy wells until the energy of the conformational change is surpassed by the energy penalty. However, the linear decrease in the target RMSD gives the simulation time to catch up. This does not allow for an unbiased calculation of the amount of time that is required for a specific conformational change. The amount of time required for a conformational change would allow for a more quantitative measure of the favorability of a conformational change. This type of simulation requires the use of a non-linear target RMSD, which would also cause a non-constant energy penalty throughout the simulation causing more unfavorable conformational changes to be allowed near the beginning of the simulation, but not at the end. While these simulations will be attempted in addition to TMD on the remaining three ASL constructs, there are caveats with both systems and careful consideration to the results of both should be made.

3.5.3 Conclusions

After thorough investigation of the structural, biophysical and functional consequences of ASL^{Arg1}_{ICG} modifications, their purpose and mechanisms had not been fully elucidated [25]. Here, we have shown computational evidence that these small modifications can modulate the residue-specific flexibility of each ASL construct. It is also the case that each necessary structure that the ASL must adopt has characteristic modification-dependent effects on structural dynamics. Additionally, the distribution of the five conserved conformational pathways that the ASL follows between the solution UNCG motif and the canonical U-turn

conformation is modification-dependent. Our results indicate that the role for modifications in this ASL is to specifically regulate residue-specific conformational space and the energy landscape between different, necessary conformations.

3.6 Methods and materials

3.6.1 Initial structures and force field parameters

Standard explicit solvent molecular dynamics simulations were carried out using the AmberTools1.5 and AMBER11 program suites [26]. For simulations of ASLs using the solution structures as a starting point, structure coordinates for unmodified ASL^{Arg}_{ACG} (2KRP), ASL^{Arg}_{ACG-s²C₃₂} (2KRW), ASL^{Arg}_{ICG} (2KRQ) and ASL^{Arg}_{ICG-s²C₃₂} (2KRV) [25]. For all of these, the representative structure was used as the starting coordinates. Starting coordinates for the three remaining ASLs, ASL^{Arg}_{ACG-m²A₃₇}, ASL^{Arg}_{ICG-m²A₃₇} and ASL^{Arg}_{ICG-s²C₃₂;m²A₃₇} were generated by editing the protein data bank files for ASL^{Arg}_{ACG} (2KRP), ASL^{Arg}_{ICG} (2KRQ) and ASL^{Arg}_{ICG-s²C₃₂} (2KRV), respectively. Starting coordinates for the synthetase-bound and ribosome-bound structures were generated by deleting all but ASL^{Arg}_{ICG} and editing the corresponding residues of PDB entry 1F7U [22] and 1XNQ [23], respectively. Poor density of the terminal residues in the heptadecamer ASL results in the crystal structure being truncated to 11 residues. To account for this, the additional stem residues were added based on positioning of the atoms in the solution structure. Constructs were then neutralized with 16 sodium ions and solvated in an octahedral box of TIP3P water [31] with a 10.0 Å cutoff. The AMBER ff99SB force field, which uses the same nucleic acid parameters as Cornell et al [32,33], was used for the common nucleosides and force field parameters for the modified nucleosides were obtained from the Modified Nucleic Acid Parameters Database [34].

3.6.2 Standard molecular dynamics simulations

Minimization and equilibration were each conducted in two steps. During the first minimization, 1000 total steps of minimization were performed with 500 steps of steepest

descent minimization and a Particle Mesh Ewald (PME) implementation of constant volume periodic boundaries [35]. Also, the RNA was held fixed with a positional restraint of 500 kcal/mol*Å². In the second step of minimization, 15000 steps of minimization were performed with 1000 steps of steepest descent and the RNA was left unrestrained. The gradual heating of the system from 0 K to 300 K was carried out during the first step of equilibration for a total of 20 ps at a time step of 2 fs while holding the RNA fixed with a weak positional restraint of 10 kcal/mol*Å². This temperature was chosen because it is closer to physiological conditions for *E.coli* than that used for both NMR and crystallography, but not too high that it introduced significant artifacts during the equilibration. For the first equilibration the PME implementation was used for a constant volume periodic boundary and for the second equilibration and production simulations, the PME implementation was used for a constant pressure periodic boundary. The SHAKE algorithm was used to constrain all bonds involving hydrogen [36] and Langevin dynamics was used at a collision frequency of 1.0 ps⁻¹ to control the temperature of the system. A second equilibration was used to relax the system for 100 ps under production conditions. Five independent production simulations were performed for a total of 6 ns (one simulation of 1 ns and a second simulation of 5 ns) using the final equilibration coordinates. All data analysis and statistical calculations were performed on the final 5 ns of each independent simulation to allow for 1 ns of further system equilibration. The use of Langevin dynamics adds the possibility of synchronization artifacts of the simulations; therefore, a random seed was used for all equilibration and production simulations [37,38]. For all steps of simulation, a non-bonded cutoff of 10.0 Å was used.

3.6.3 Targeted molecular dynamics simulations

All TMD simulations were performed with directionality starting from the fully equilibrated solution structures (after 120 ps of equilibration and 6 ns of production simulation) and ending with fully minimized ribosome-bound or synthetase-bound structures. The identity of the independent simulation that was used for TMD was determined based on convergence of the standard simulations. For TMD simulations, the total number and identity

of atoms in the initial structure and the reference structure must match exactly. While the initial structure will contain the same amount of atoms in the ASL and the same number of Na⁺ ions, the number of waters will be different because the difference in conformation will require a different radius of the TIP3P octahedral water box. To account for this, a truncated octahedral box of TIP3P water was used with a radius that gave a slightly larger number of water molecules than was necessary. The unnecessary water molecules were then deleted prior to producing the input coordinates. VMD was used to determine the starting RMSD and rounded down to the nearest 0.5 Å for the starting target RMSD. Simulation times were variable such that the target RMSD was reduced linearly at a rate of 0.5 Å/ns until reaching 0.0 Å followed by a full 1 ns of simulation at 0.0 Å using a force constant of 1.0 kcal/mol*Å². Simulations were performed at a constant 300 K and 1 atm with a 2 fs time step using the SHAKE algorithm [36] using random seeds. Trajectories were analyzed using ptraj [26], visualized using VMD [39] and PyMol [40] and plotted using Grace.

3.7 Acknowledgements

The authors would like to acknowledge the contributions of Dr. F.A.P. Vendeix, Dr. A. Chen and Dr. J. Schipper for their technical expertise and helpful discussions. Also, E. Warnke and A. Shelton of the University at Albany Research IT Department for their technical assistance and software troubleshooting.

Table 2. Distribution of conformational pathways for each ASL construct.

Pathway	ACG	ACGm2A	ACGs2C	ICG
1	40%	40%	---	---
2	60%	---	---	---
3	---	20%	40%	40%
4	---	20%	20%	---
5	---	20%	40%	60%

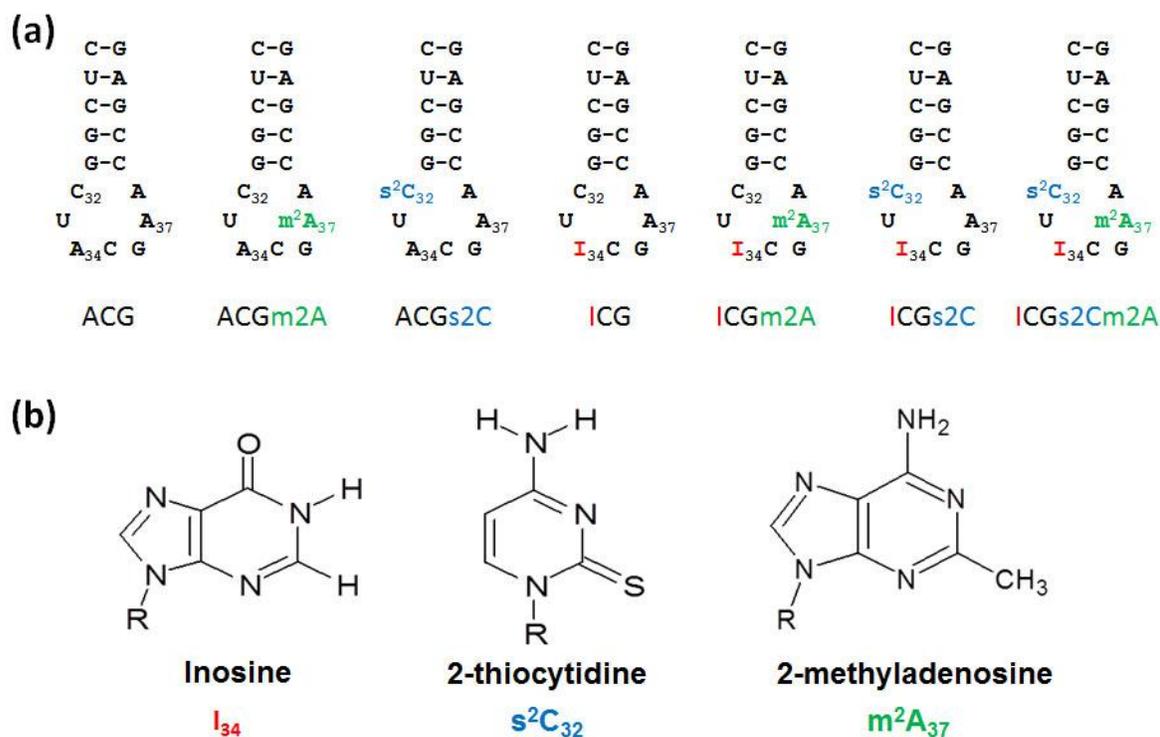

Figure 1. ASL constructs and nucleoside modifications. (a) Seven differentially modified ASL constructs were used for molecular dynamics simulations. The naming conventions below each ASL are used in other figures and text and denote the three anticodon residues followed by position 32 and 37 modifications 2-thiocytidine (s2C) and 2-methyladenosine (m2A). (b) The modified nucleosides present in these ASLs are all small modifications. Inosine is a deaminated adenosine in which the position 6 amine is converted to a carbonyl. In 2-thiocytidine, the carbonyl at position 2 is converted to a thionyl. A methyl group is added to the number 2 carbon of adenosine to create 2-methyladenosine.

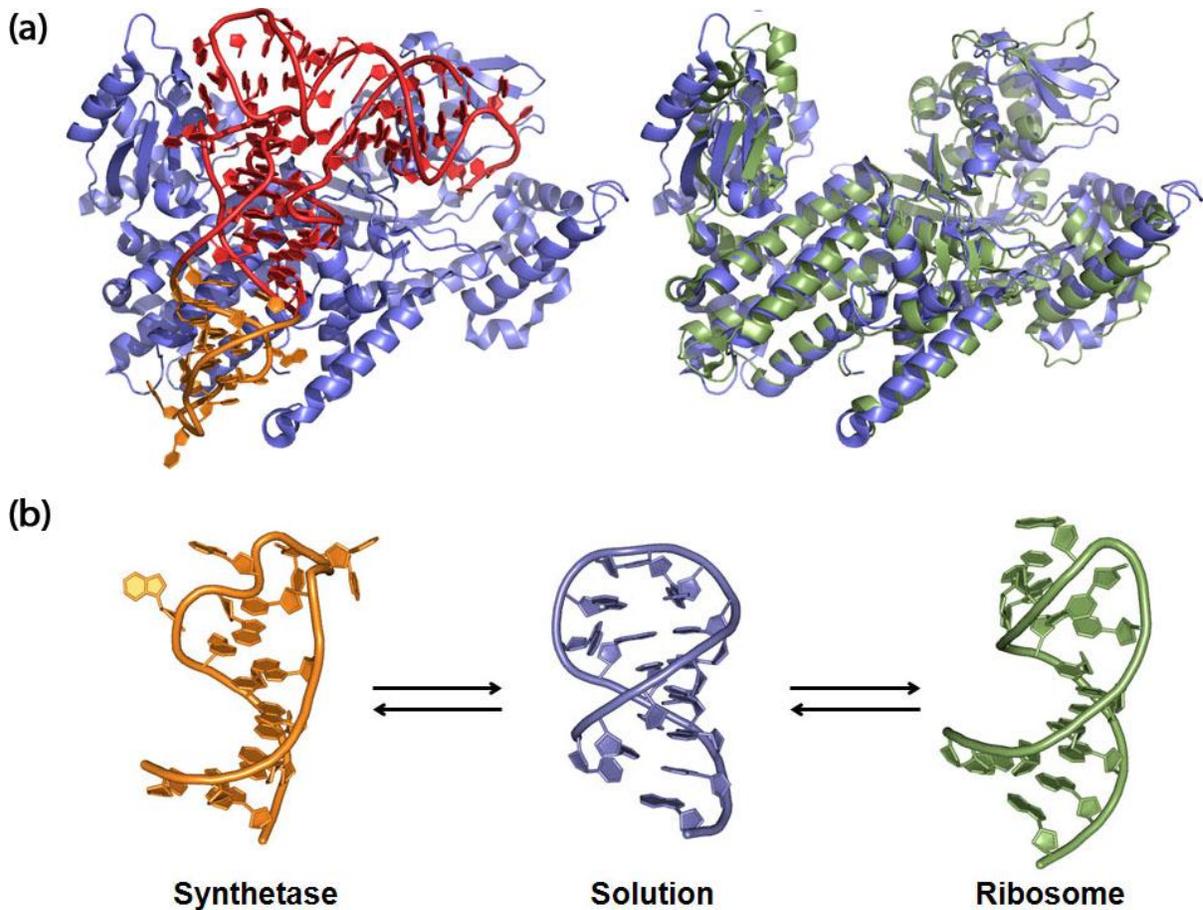

Figure 2. Structural studies have identified three different conformations that must exist within the cell. (a) The crystal structures of the yeast arginyl-tRNA synthetase (blue) with tRNA^{Arg}_{ICG} (red) showing the location of the ASL (orange) on both structures (left) and superimposed with the bacterial synthetase (green) showing homology in the ASL binding region (right). **(b)** An equilibrium must be present between the structure in solution (blue, middle), the canonical U-turn conformation when bound in the ribosomal A-site (green, right) and distorted structure seen when bound to the yeast aminoacyl-tRNA synthetase (orange, left). To achieve proper function, the ASL must be able to switch between the three conformations in a reversible manner.

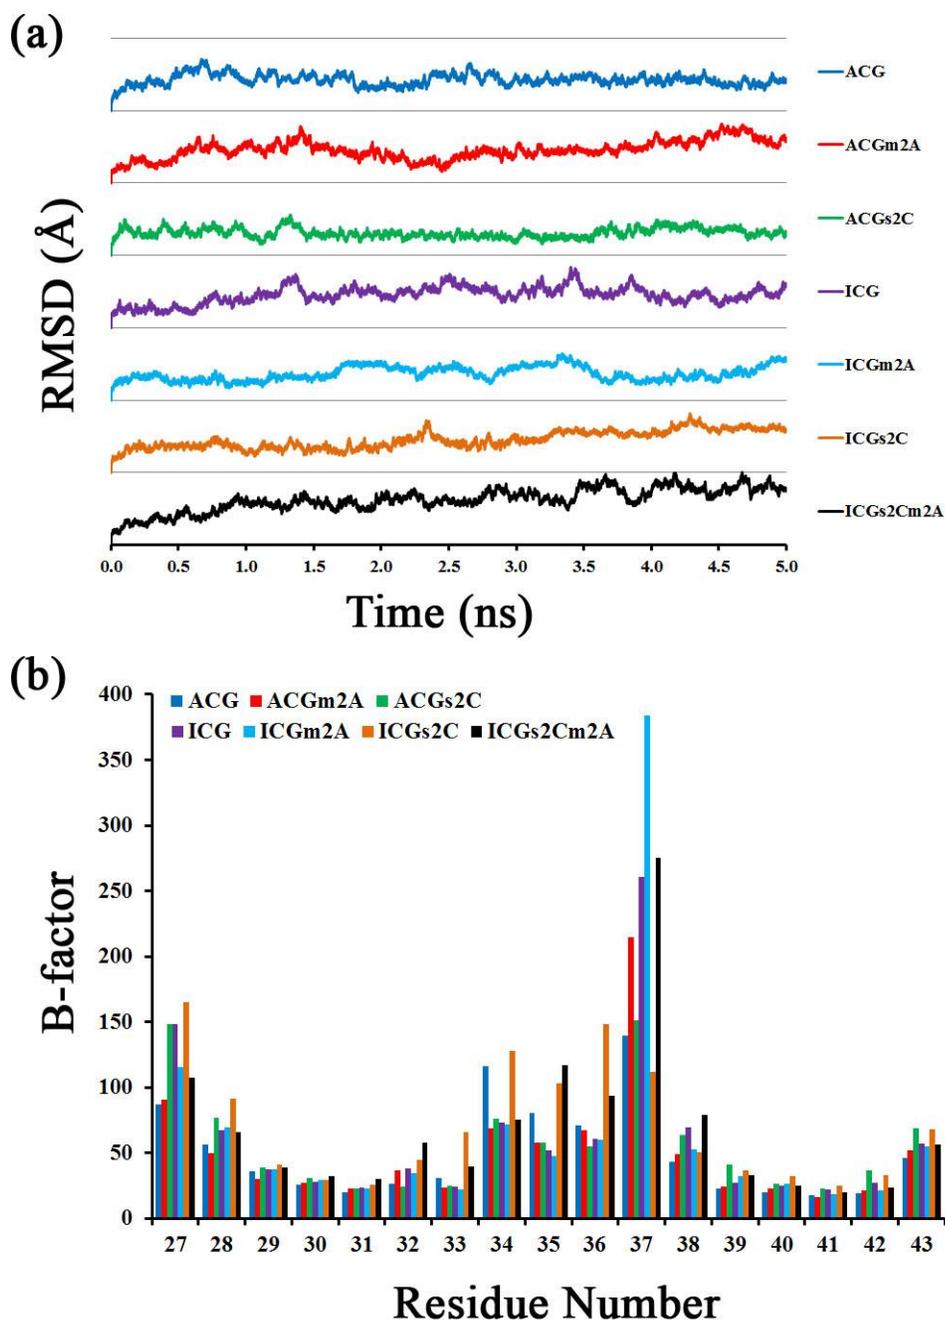

Figure 3. Standard MD simulations of the ASL^{Arg1}_{ICG} solution structure. (a) Representative heavy atom RMSD vs time plots over 5ns showed only slight variations. (b) Per residue B-factor calculations allowed for a determination of the residue-specific flexibility in the loop. B-factors were calculated based on root mean square fluctuations using the ptraj module from AmberTools1.5. The average of five replicates is plotted.

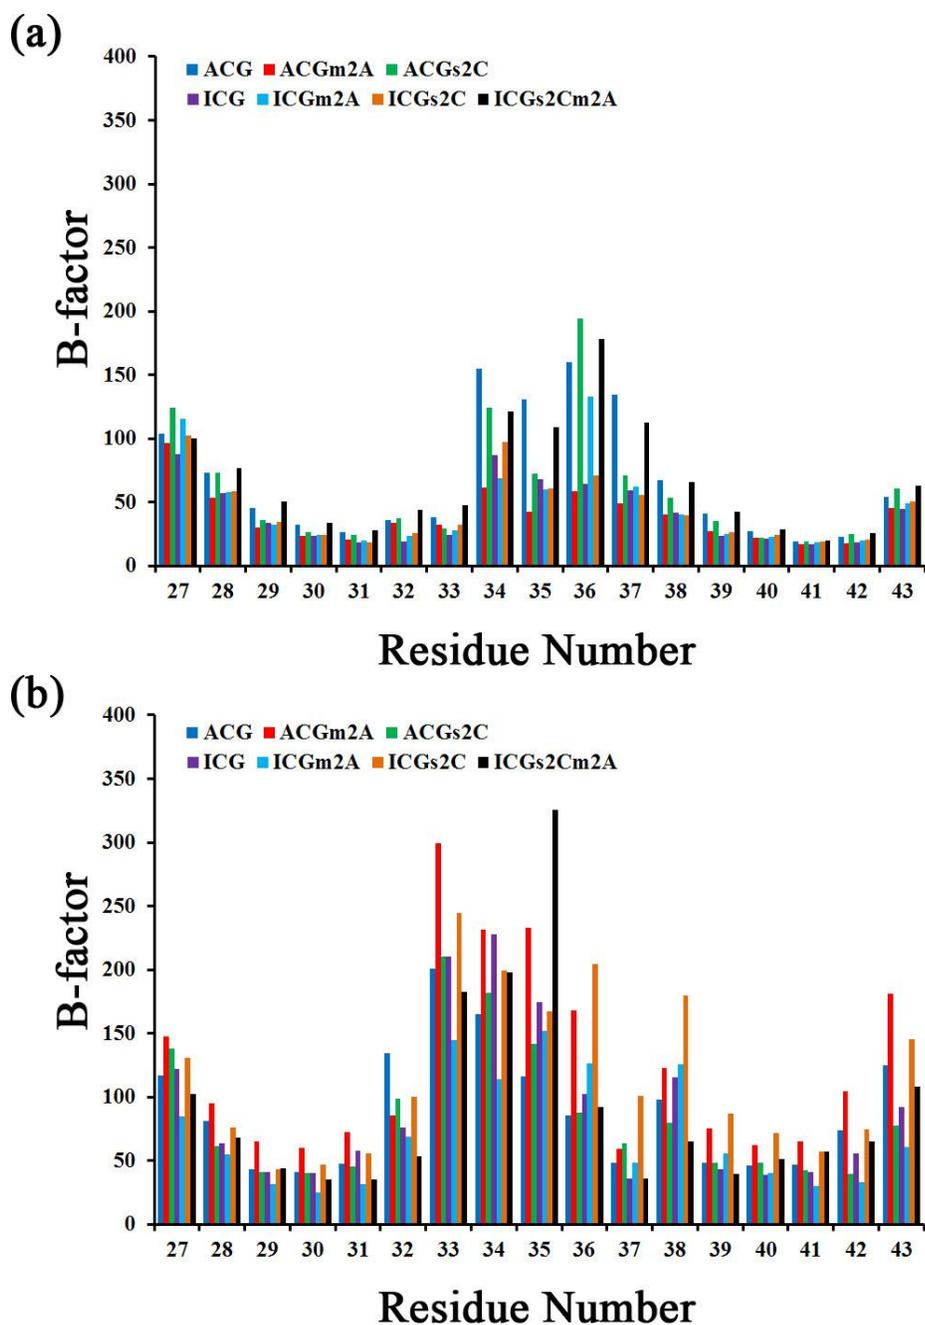

Figure 4. Standard MD simulations of the ASL^{Arg1}ICG ribosome-bound and synthetase-bound structures. The per residue B-factors were calculated from 5ns of standard molecular dynamics simulations using the (a) ribosome-bound U-turn and (b) distorted, synthetase-bound conformations as starting structures for determination of residue-specific conformational space. B-factors were calculated based on root mean square fluctuations using the ptraj module from AmberTools1.5. The average of five replicates is plotted.

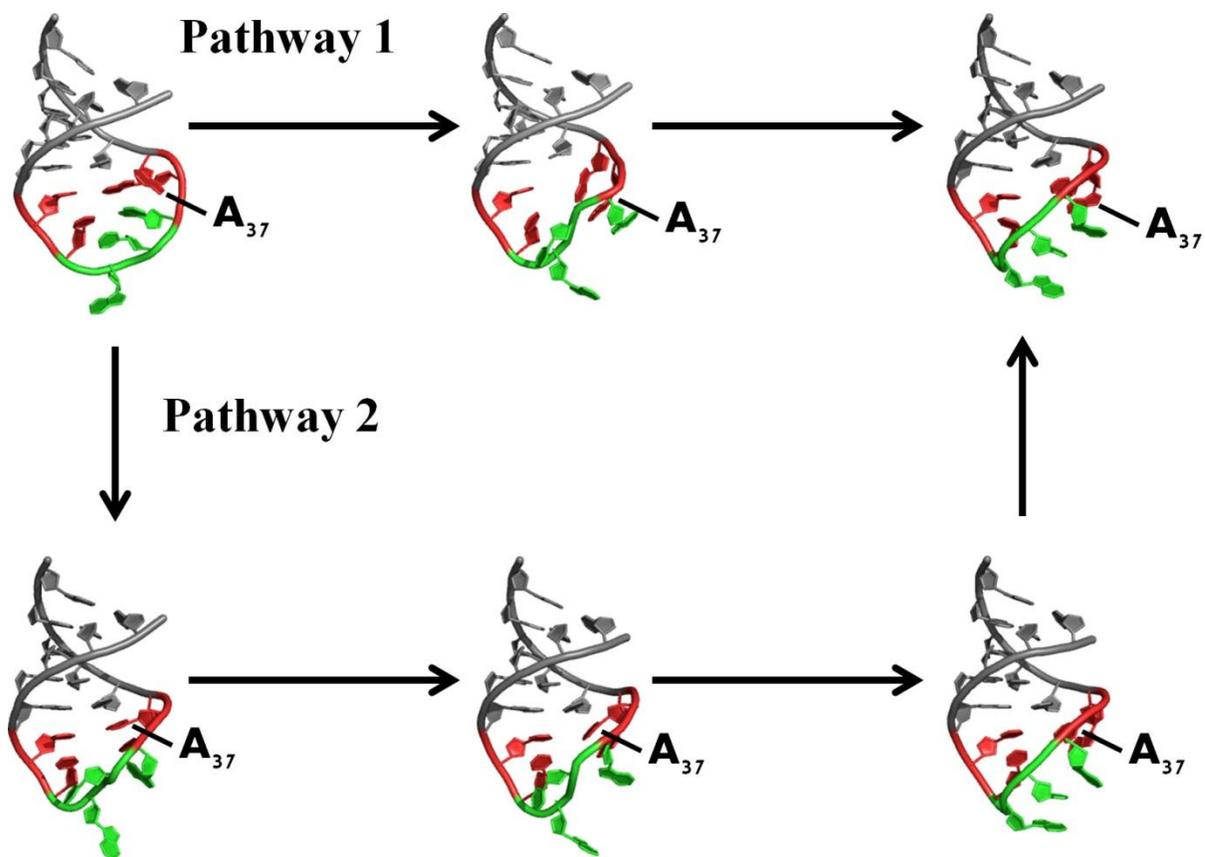

Figure 5. Conformational pathways resulting in a canonical U-turn structure. Pathway 1 is characterized by A₃₇ flipping from a solvent-exposed position to stacking between G₃₆ and A₃₈ as G₃₆ flips from the inside to the outside of the loop and into the anti glycosidic conformation. In Pathway 2, A₃₇ takes the unusual position of stacking between A₃₈ and C₃₉, displacing the C₃₂•A₃₈ non-canonical base pair, forming a Watson-Crick•Hoogsteen C₃₂•A₃₇ base pair. Next, G₃₆ has room to flip outside of the loop and into the anti glycosidic rotation, followed by C₃₅ flipping outside of the loop and stacking with A₃₄ and G₃₆. Finally, the C₃₂•A₃₇ base pair is destabilized by the flipping of C₃₅ causing A₃₇ to stack between G₃₆ and A₃₈ and resulting in the reformation of the C₃₂•A₃₈ base pair.

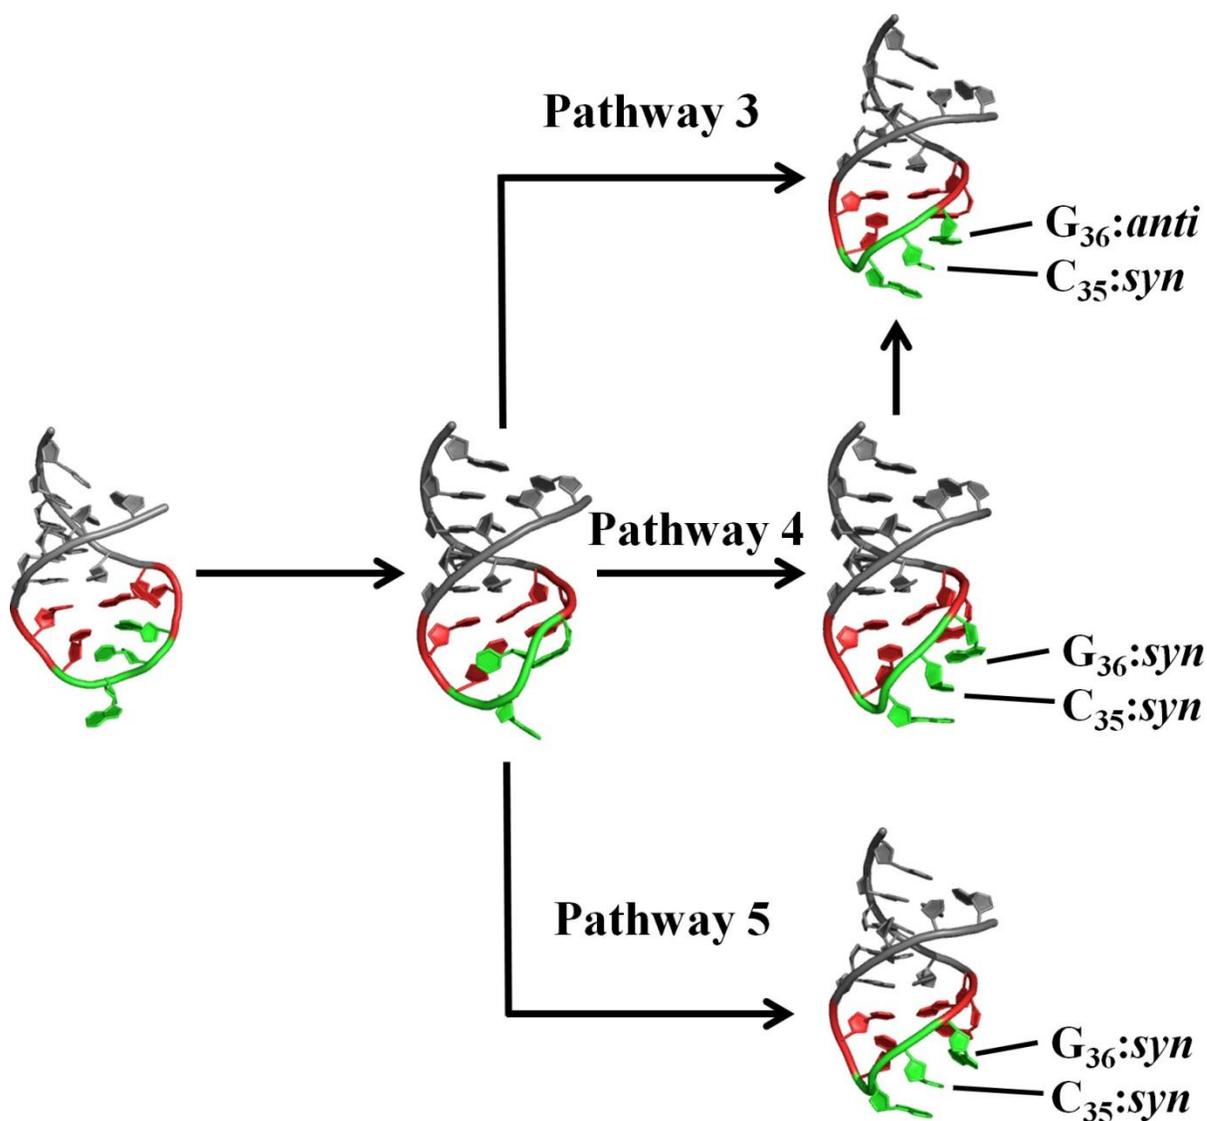

Figure 6. Conformational pathways not resulting in a canonical U-turn structure. In all three pathways, the first step occurs with A₃₇ flipping between G₃₆ and A₃₈ while G₃₆ flips from the inside to the outside of the loop and adopts a *syn* glycosidic conformation. In **Pathway 3**, G₃₆ flips from *syn* to *anti*-conformation when C₃₅ flips outside of the loop and stacks with A/I₃₄ and G₃₆. **Pathway 4** is characterized by a more sequential change in which C₃₅ flips outside the loop prior to G₃₆ rotating from *syn* to *anti*. In **Pathway 5**, C₃₅ moves from inside of the loop to outside of the loop as in Pathway 4; however, G₃₆ never adopts the *anti*-conformation.

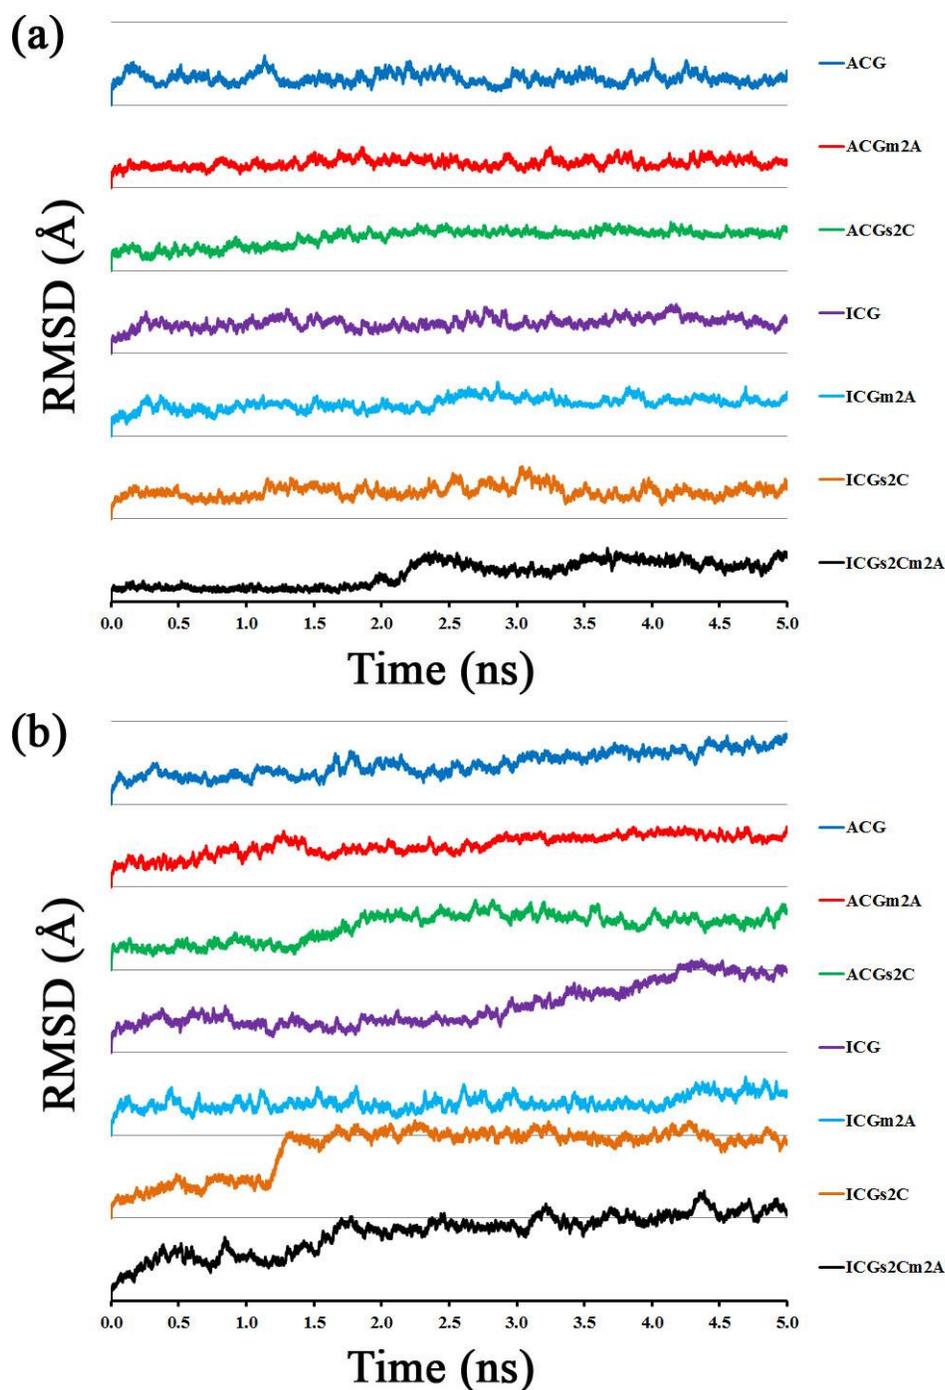

Figure S1. Standard MD simulations of the ASL^{Arg1}_{ICG} ribosome-bound and argRS-bound structures. Representative heavy atom RMSD vs time plots over 5ns showed only slight variations in standard MD simulations using starting structures from both (a) the ribosome-bound U-turn conformation and (b) argRS-bound distorted conformation.

CHAPTER 4. Structure and function effects of tRNA^{Arg4}_{UCU} anticodon domain modifications

To be submitted once completed with the following authorship:

William A. Cantara, Kun Lu , Minhal Makshood, Erick Harr, Rob Kaiser, Paul F. Agris

4.1 Statement of project contribution

I, along with Dr. Agris, acted in a supervisory role for this project. I personally performed the thermal denaturation, circular dichroism and ribosome binding experiments. I also assisted with the NMR experiments and spectral assignments by assigning the ribose resonances. I will also be performing the structure calculations. I had the help of Dr. Kun Lu, who performed all of the NMR experiments and assigned all the aromatic protons of the RNAs. Minhal Makshood and Erick Harr, two undergraduates assisted with the circular dichroism and thermal denaturation experiments, respectively. I acted in an advisory and mentoring role for both undergraduates and coordinated experiments with Dr. Lu.

Abbreviations: ASL, anticodon stem and loop; CD, circular dichroism spectroscopy; COSY, COrelation Spectroscopy; HSQC, Heteronuclear Single Quantum Correlation; mnm⁵U₃₄, 5-methylaminomethyladenosine in position 34; mRNA, messenger RNA; NMR, nuclear magnetic resonance; NOE, Nuclear Overhauser Effect; NOESY, Nuclear Overhauser Enhancement Spectroscopy; ppm, part per million; RMSD, root mean square deviation; s²C₃₂, 2-thiocytidine in position 32; t⁶A₃₇, 2-methyladenosine in position 37; TOCSY, TOtal Correlation Spectroscopy; Ψ₄₀, pseudouridine in position 40.

Keywords: RNA structure, RNA function, 2-thiocytidine, 5-methylaminomethyladenosine, N⁶-threonylcarbamoyladenine

4.2 Abstract

In *Escherichia coli*, tRNA^{Arg4}_{UCU} is responsible for decoding the rare AGA codon. The anticodon stem and loop domain of this isoacceptor contains the three common modifications mnm⁵U₃₄, t⁶A₃₇ and Ψ₄₀ as well as the rare s²C₃₂. Here unmodified ASL^{Arg4}_{UCU}, singly modified ASL^{Arg4}_{UCU}-s²C₃₂ and ASL^{Arg4}_{UCU}-mnm⁵U₃₄;t⁶A₃₇;Ψ₄₀ were investigated using a combination of functional, biophysical and structural techniques to decipher the structural and functional characteristics that are imparted by these modifications. Codon-specific ribosome binding assays confirm that binding to the cognate AGA codon is dependent on modification. Although s²C₃₂ has an inhibitory effect on wobble decoding in tRNA^{Arg1,2}_{ICG}, it is not responsible for negating dual codon recognition of both AGA and AGG in tRNA^{Arg4}_{UCU}. Biophysically, these modifications decrease molecular stability and base stacking interactions at optimum growth temperature, but increase the overall melting temperature. Interestingly, s²C₃₂ elicits an extra low temperature melting transition that is characterized by a significant change in secondary structure. To gain a better understanding of the structural properties of these modifications, NMR studies were performed to compare the structure difference between modified and triply-modified tRNA^{Arg4} ASL. Preliminary NMR results suggest that the hypermodified nucleosides introduce more stability to the structure and promote a rigid loop conformation, which is important for codon-anticodon interaction. The modifications also affect the formation of C₃₂•A₃₈⁺ at the base of the anticodon stem by affecting the pKa of A₃₈. Although a spectral characteristics of a canonical U-turn were not observed, several NOEs have been observed between mnm⁵U₃₄ and t⁶A₃₇, which may indicate preorganization of the ASL for codon recognition, reducing the entropic cost of an induced fit in the ribosomal A-site. A full molecular dynamics-restrained NMR solution structure determination of all three ASLs is underway to unambiguously determine the roles of these modifications in the structure: function relationships of this ASL.

4.3 Introduction

Proper and efficient ribosome-mediated protein synthesis relies on the correct 3-dimensional structure and chemistry of tRNA. Studies aimed at detailing the role of tRNA structure and function in translational fidelity have led to the discovery of 93 different naturally occurring modifications present in tRNA [1]. While these modifications, in general, lead to increased order and stability for the molecule as a whole, the great number and diversity of modification chemistries in the anticodon stem and loop (ASL) leads to a variety of translational properties. Indeed, ASL modifications can act as identity determinants for aminoacylation [2], enhance stability [3,4], maintain the translational reading frame [5,6], regulate codon discrimination [7,8], increase synonymous codon affinity [9-11] and prestructure the ASL into a canonical U-turn for proper ribosomal A-site recognition [4].

Translational decoding of rare codons has implications for understanding both epigenetic regulation of gene expression and evolution of codon bias. A compelling trend exists between tRNA expression patterns and codon bias in both *E.coli* and yeast [12]. This study revealed that in *E.coli* tRNA^{Arg3}_{CCU} and tRNA^{Arg4}_{UCU}, which are responsible for decoding the rarest codons, AGG and AGA, are the most scarcely expressed tRNAs. A regulatory role is evident by the DNA synthesis and repair, protein synthesis, cell cycle regulation and metabolism genes that are enriched with these rare codons [13]. Indeed, genes enriched with these codons show reduced levels of translation and a high frequency of translational frameshifting events [14,15].

The *E.coli* tRNA^{Arg4}_{UCU} ASL contains four endogenous posttranslational modifications, 2-thiocytidine at position 32 (s²C₃₂), 5-methylaminomethyluridine at position 34 (mm⁵U₃₄), N⁶-threonylcarbamoyladenine at position 37 (t⁶A₃₇) and pseudouridine at position 40 (Ψ₄₀) (Figure 1a) [16]. The rare s²C₃₂ modification is found in four of the five arginyl-tRNA isoacceptors and tRNA^{Ser2}_{GCU} in *E.coli*, making it of particular interest [16]. The oxygen to sulfur replacement at position 2 of pyrimidines further stabilizes a C3'-endo sugar pucker in addition to an *anti* N-glycosidic conformation [17-20]. Also, the lower electronegativity of the sulfur atom results in better stackability of the base [21]. Interestingly, these properties

should stabilize the cross-loop C₃₂•A₃₈ mismatch base pair that commonly closes the loop, resulting in a pseudo five-membered loop that is characteristic of a canonical U-turn conformation [22,23].

In addition to s²C₃₂, ASL^{Arg⁴}_{UCU} contains two other loop sequence and modifications that closely match those seen in a hypomodified *E.coli* ASL^{Lys}_{UUU} (Figure 1b). In ASL^{Lys}_{UUU}, the mnm⁵U₃₄ and t⁶A₃₇ modifications confer the ability to read both A and G in the third codon position [10]; whereas, in ASL^{Arg⁴}_{UCU}, it only allows recognition of A [15]. It has been shown that the geometry of the C₃₂•A₃₈ mismatch base pair regulates the ability of the ASL to discriminate between cognate and wobble codons [24]. Therefore, the presence of s²C₃₂ may alter the geometry of this pair, rendering the ASL incapable of decoding the other rare AGG codon in addition to AGA. Indeed, s²C₃₂ has been shown to have an inhibitory effect on wobble binding of ASL^{Arg¹}_{ICG} to the rare, synonymous CGA codon [7]. ASL^{Lys}_{UUU} also has the uncommon property of forming an extended stem conformation resulting in a trinucleotide loop in the absence of modification [25]. In that case, the modifications mnm⁵U₃₄ and t⁶A₃₇ functioned to negate intraloop hydrogen bonding and stabilizing a prestructured U-turn-like conformation in solution [4,25,26].

To investigate the roles of posttranscriptional modifications in the structure and function of ASL^{Arg⁴}_{UCU}, thermodynamic, functional and structural characterizations were performed on synthesized unmodified (ASL^{Arg⁴}_{UCU}), singly modified (ASL^{Arg⁴}_{UCU}-s²C₃₂) and triply modified (ASL^{Arg⁴}_{UCU}-mnm⁵U₃₄;t⁶A₃₇;Ψ₄₀)(Figure 1c). Codon binding assays revealed that s²C₃₂ was not responsible for negating the ability of the ASL to wobble decode AGG codons; however, biophysical experiments suggest that it may play a role in modulating the thermal stability of certain secondary structure elements. Despite a lack of characteristic U-turn spectral identifiers, the remaining three modifications appear to stabilize the loop residues into a more ordered conformation, reducing the energetic resources required for adopting a canonical U-turn conformation for A-site ribosome binding.

4.4 Results

4.4.1 Lack of s^2C_{32} does not allow wobble decoding

Two key differences between the loops of ASL^{Arg4}_{UCU} and ASL^{Lys}_{UUU} are the modification of C₃₂ to s^2C_{32} in ASL^{Arg4}_{UCU} and difference in the identity of the pyrimidines at position 35 of the anticodon (Figure 1a,b). To determine if, as seen in ASL^{Arg1}_{ICG}, the s^2C_{32} is responsible for the restriction of binding to AGA only, A-site codon specific ribosome binding assays were performed on three synthesized ASL constructs (unmodified ASL^{Arg4}_{UCU}, singly modified ASL^{Arg4}_{UCU}- s^2C_{32} and triply modified ASL^{Arg4}_{UCU}-mnm⁵U₃₄;t⁶A₃₇;Ψ₄₀; Figure 1c). Neither the unmodified nor the singly modified ASLs were able to bind to the AGA codon; however, the triply modified ASL bound AGA with a dissociation constant of 188 ± 21 nM (Figure 2a). Interestingly, none of the ASL constructs tested, including the triply modified ASL^{Arg4}_{UCU}-mnm⁵U₃₄;t⁶A₃₇;Ψ₄₀, were able to bind to the AGG codon efficiently (Figure 2b), a clear indication that s^2C_{32} is not responsible for negating wobble decoding of AGG. Dissociation constants were able to be determined for some of the other ASL constructs; however, the relatively low amount of binding suggests that these are not physiologically relevant binding events.

4.4.2 Modifications alter biophysical properties of the ASLs

Ribosomal A-site codon binding assays revealed that modifications are required for binding to the cognate AGA codon. To assess the biophysical characteristics caused by modification, circular dichroism and UV-monitored thermal denaturation spectroscopies were performed on all three ASL constructs. One of the hallmark characteristics of the canonical U-turn structure is the presence of a highly stacked and ordered loop; therefore, circular dichroism spectroscopy was used to measure the relative amount of stacking in each construct. All ASLs showed a peak around 270 nm indicating that they all form an A-form RNA stem; however, the triply modified ASL peak was slightly red-shifted suggesting that the modifications may be inhibiting a cross-loop hydrogen bond [27]. The unmodified ASL showed the largest peak ($7.53 \text{ cm}^2/\text{mmol}$), corresponding to a high level of base stacking,

compared to the triply modified ASL (6.46 cm²/mmol) at 5°C (Figure 2c). Interestingly, when heated up to 20°C, the ellipticity of both the unmodified and triply modified ASLs decreased by ~5%, whereas the ellipticity of the singly modified ASL dropped by 16.3% (Figure 2c,d). This indicates that, individually, the s²C₃₂ is forming base stacking interactions at low temperature that are easily broken with a small temperature increase.

Both the singly modified and triply modified ASLs showed both a reduction of ~1.5% hyperchromicity (Table 1, Figure 3), a measure of the overall molecular order. Correspondingly, the unmodified ASL showed a more negative enthalpy and free energy change, suggesting that the extra order may result in stabilization of the ASL. Interestingly, the higher melting temperature of triply modified ASL^{Arg4} indicates that the pseudouridine or other modifications are acting to inhibit full melting of the hairpin, independent from the structural order. This is a common property of pseudouridine in A-form RNA helices [4,28]. Although thermodynamic parameters were not calculated for the singly modified ASL, the melting curve reveals a low temperature transition that corresponds with the circular dichroism data (Figure 3). Overall, the biophysical data reveals a modification dependent modulation of the thermodynamic and base stacking properties of the ASL constructs, resulting in a reduction of overall molecular order and reduction in the base stacking of the loop.

4.4.3 NMR resonance assignments

Biophysical characterization suggests that the differences in codon binding seen in the ASLs are related to modification-induced alteration of loop conformation. Specifically, modifications may play a role in reorganizing the loop residues to allow for proper A-site recognition [4,29]. To understand whether structural differences exist and how they may influence codon discrimination, full nuclear magnetic resonance spectroscopy (NMR) characterizations were performed on the unmodified and triply modified ASL constructs. Commonly used protocols for establishment of nucleic acid resonance assignments in the absence of isotope labeling were applied [30-33]. Using a combination of ¹H-¹H homonuclear and natural abundance ¹H-¹³C and ¹H-³¹P heteronuclear NMR experiments,

sequence-specific assignment of nucleotide spin systems were mostly completed.

Exchangeable proton spectra were recorded in 90% H₂O/10% D₂O at three different temperatures (283K, 288K and 293K) to observe and identify the imino and amino resonances of the stem residues. The imino signal assignments are consistent with the formation of the predicted five base-pair double-stranded stem region in both unmodified and triply modified ASL^{Arg4} RNAs. Five well-resolved peaks were observed in the low field region (12.00-14.50ppm) of the 1D imino spectra of both unmodified and triply modified ASLs. These were identified as the base-paired stem residue protons G₂₇H1, G₂₉H1, G₃₉H1, U/ Ψ ₄₀H3 and G₄₂H1 (Figure 4). No additional imino protons were observed in both samples that would indicate the presence of alternate conformations typically seen in mixtures of hairpin and duplex. In both spectra, one initially broad peak that was significantly broadened by a temperature increase was assigned to G₂₇H1 as this is a characteristic feature of the terminal base pair which rapidly exchanges with solvent. Three additional peaks were observed in the triply modified ASL spectrum as a result of t⁶A₃₇ and Ψ ₄₀ (Figure 4b). The amide proton resonances at 9.1 and 10.1 ppm were assigned to be N6H and N11H of t⁶A₃₇ from 2D NOESY and TOCSY connectivities. The N11H resonance of the ureido of the threonyl moiety of t⁶A₃₇ was observed and has TOCSY connectivity to the H α and H β resonances of the side chain, indicating that N11 acts as a hydrogen bond donor with N1 on the Watson-Crick face. The observation of t⁶A₃₇ N6H and N11H indicated that the remaining peak at ~10.3 ppm was assigned to N1H of Ψ ₄₀. The N1H imino protons have been observed and assigned in a number of tRNAs [34-36], tRNA anticodon stem-loop [37], single-stranded RNA [38] and RNA duplexes [39,40]. To observe the Ψ ₄₀ N1H, the only structural requirement is that the local structure in the vicinity of Ψ allows for an RNA conformation with two phosphates in position for water coordination. Therefore, the observation of uridine N1H in the triply modified ASL^{Arg4} suggests that the Ψ modification provides additional stabilization to the RNA structure most likely through coordination of a water molecule and the imino proton exchange is sufficiently slowed to allow detection of the Ψ ₄₀ N1H NMR resonance. The imino and amino protons in the loop residues were not observed due to their rapidly exchanging nature.

The pH effect on the chemical shift of the unmodified ASL^{Arg4} exchangeable protons was characterized at three different pHs of 6.8, 6.0 and 5.5 at 288K (Figure 6a). No dramatic changes were observed for G₂₇H1, G₂₉H1, U/Ψ₄₀H3 and G₄₂H1, however, G₃₉H1 showed a significant downfield shift corresponding to the pH decrease, indicating the environment of the G₃₉H1 is sensitive to the pH change. The A₃₈, 5' base of G₃₉, could form an A⁺-C base-pair with C₃₂. To investigate if an A₃₈⁺-C₃₂ base-pair forms in ASL^{Arg4} and the protonation of A₃₈ affects the G₃₉H1 chemical shift, we collected the pH-dependent HSQC spectra (Figure 6b). ¹H-¹³C HMQC spectra confirms formation of an A⁺-C base-pair with protonation at N1 of A₃₈ as evidenced by an unusual ¹³C chemical shift of ~ 6-7 ppm for the C2 of A₃₈ upon decreasing the pH to 5.5 [28,41]. At pH 6.8, A₃₈C2 is involved in exchanging between protonation and deprotonation and is completely broadened out, indicating the pKa of A₃₈H1 is around 6.8. The ¹³C chemical shifts of the C₃₂ C5 and C6 carbons remain unchanged upon lowering the pH (data not shown), consistent with protonation of A₃₈ rather than C₃₂. Our NMR results confirmed the formation of the A⁺-C base-pair and it stabilizes the unmodified ASL^{Arg4} structure. The high pKa of A₃₈ affects loop structure even at neutral pH, suggesting that the A⁺-C base-pair formation may be biologically relevant. Due to the risk of destabilizing the modified nucleotides under low pH, we haven't decreased the pH of the triply-modified ASL^{Arg4} to study the pH effect on its structure. However at neutral pH, a broadened but detectable resonance with an unusual ¹³C chemical shift was observed for A₃₈C2-H2 in the ¹H-¹³C HMQC spectra indicating an elevated pKa (data not shown).

A series of NOESY spectra recorded in 100% D₂O at various mixing times from 50 ms to 400 ms were collected for the assignment of non-exchangeable protons in the ribose and base ring. DQF-COSY were also collected to identify intranucleotide connectivities. These homonuclear experiments were used to assign resonances via the "sequential walk" method (Figure 5), starting from the 5'-terminus. A characteristic NOE walk was observed between G₂₇H1'-H8 and C₃₂H1'-H6 and from U₃₆H1'-H6 to C₄₃H1'-H6 for both unmodified and triply modified ASL^{Arg4}. The assignments of the H2' resonances were confirmed through observation of the strong cross-peaks to the H1' protons in the short mixing time NOESY experiment. The H3' protons were identified using the ¹H-¹³C HSQC experiments. A nearly

complete assignment of each nucleotide's proton resonances was accomplished using the sequential connectivity of the H1'-H8/H6, H2'-H8 and H3'-H8 NOE cross peaks to assign the H1', H2' and H3' protons. The remaining anomeric protons (H4' and H5'/H5'') were assigned on the ^1H - ^{13}C HSQC spectra by their distinctive ^{13}C chemical shift. Due to severe resonance overlaps, only a partial assignment of the H4' and H5'/H5'' protons was achieved.

From the assigned non-exchangeable protons, breaks in the sequence between the connectivity of C₃₂ to C₃₅ were observed in both ASLs. A₃₈H2-U₃₃H1' was observed in the NOESY spectra of both ASLs indicating the extended hairpin formation in the loop region. The G₃₉H8-G₃₉H1' peak is much broader for the unmodified ASL^{Arg4} when compared to the triply-modified, suggesting the modifications introduced more stabilization to the ASL structure. The characteristic connectivity of U₃₃H1'-C₃₅H8 NOE that is routinely associated with the canonical U-turn motif of tRNA anticodon was not unambiguously observed. The canonical conformation for the 33p34 phosphate is one where the α dihedral angle is trans [42], and this can be conveniently monitored by ^{31}P NMR because a downfield shift is seen for the phosphate in a U-turn structure [43,44]. However, no downfield shifted magnetic resonance was observed in the ^{31}P NMR spectra of both unmodified and triply modified ASL^{Arg4} (Figure 7).

A common feature of the U-turn conformation is the presence of a stable A-form stem and loop consisting exclusively of nucleosides exhibiting C3'-*endo* sugar pucker geometry. Therefore, the sugar pucker conformations of each residue were investigated using COSY, DQF-COSY and TOCSY (data not shown). Both the unmodified and triply modified ASLs showed similar characteristic ribose geometry properties. The five base-paired stem residues conformed to a C3'-*endo* conformation ($^3J_{\text{H1}'\text{-H2}'} < 2$) characteristic of a canonical A-form helix. Additionally, the loop residues U₃₃, U₃₆, A₃₇ and A₃₈ were in the C3'-*endo* geometry; however, U₃₃, U₃₄ and C₃₅ exhibited C2'-*endo* conformations ($^3J_{\text{H1}'\text{-H2}'} > 5$). To summarize, NMR spectroscopy was used to fully characterize the structural characteristics of both the unmodified and triply modified ASLs, neither of which showed characteristic spectral properties supporting a U-turn conformation in solution.

4.5 Discussion

4.5.1 C_{35} is a positive determinant for A/G-ending codon discrimination

Deciphering the roles of anticodon domain modifications in tRNA function is key to understanding how the genetic code is regulated and evolved. While some modifications are highly conserved for a specific purpose in many different ASLs, it has become evident that modifications are not always modular in the sense that many appear to function in a way that is dependent on the chemical environment created by the other loop residues [7,45]. A high conservation of t^6A_{37} modifications and derivatives thereof in tRNAs responsible for decoding 5'-ANN-3' codons [16] stems from the ability of this residue to form a pseudo-heterotricyclic ring that stacks on top of and stabilizes the low enthalpic $U_{36}\bullet A_1$ base pair [4]. Contrastingly, however, we show that in the context of $ASL^{Arg^4}_{UCU}$, mm^5U_{34} allows for the recognition of only the A-ending AGA codon, whereas in ASL^{Lys}_{UUU} , the same modification further increases recognition to both the A-ending AAA and the G-ending AAG codons [10].

The ability of the ASL to modulate codon discrimination at the wobble position is linked both to the geometry the position 34 sugar pucker [20,46,47] and the stem proximal non-canonical interaction between position 32 and 38 [24]. Depending on whether the position 34 modification promotes a C2'-endo or C3'-endo sugar pucker, the modification tends to either restrict or expand codon recognition, respectively [20,46,47]. In both the unmodified ASL^{Lys}_{UUU} and $ASL^{Lys}_{UUU-t^6A_{37}}$, U_{34} adopts a C2'-endo conformation, rendering the ASL unable to decode AAG. Interestingly, the methylaminomethyl modification at the 5-position of uridine does not generally promote the C3'-endo geometry in a pyrimidine rich region [48]. The wild-type ASL^{Lys}_{UUU} contains a 2-thiolation of U_{34} in addition to the mm^5 modification [16] which is the determinant that promotes the C3'-endo conformation of itself and in neighboring residues [19]. Although in ASL^{Lys}_{UUU} , the 5-position modification is sufficient to allow for recognition of both AAA and AAG, the crystal structure of this interaction shows a geometry for the $mm^5U_{34}\bullet G_3$ base pair requiring a rotation about the C1'-N1 bond that allows for a bifurcated hydrogen bond to form between N1 and N2 of the codon G_3 and O2 of mm^5U_{34} [23]. Since this interaction is much less stable than the normal

G•U wobble base pair between that is characterized by two hydrogen bonds, the base pair is characterized by a stacking interaction caused by the oxygen of the 2-position carbonyl group of $\text{mnm}^5\text{U}_{34}$ being positioned directly over the ring of U_{35} [23].

Codon specific A-site ribosome binding assays show a clear distinction between the unmodified and modified ASL in which only the triply modified ASL was able to bind AGA and none of our constructs could recognize AGG (Figure 2a,b). It is clear from previous studies that the fully modified $\text{tRNA}^{\text{Arg4}}_{\text{UCU}}$ can recognize only AGA [15]. Since our construct lacks the endogenous 2-thiolation of C_{32} , we conclude that s^2C_{32} is not responsible for negating the dual codon recognition seen in the similar $\text{ASL}^{\text{Lys}}_{\text{UUU}}$. The only remaining difference in the identities of the loops between triply modified $\text{ASL}^{\text{Arg4}}_{\text{UCU}}$ and doubly modified $\text{ASL}^{\text{Lys}}_{\text{UUU}}$ is the identity of the position 35 nucleoside. In $\text{ASL}^{\text{Lys}}_{\text{UUU}}$, the position 35 uridine is responsible for proper positioning of the modified $\text{mnm}^5\text{U}_{34}$ [23]. Thus the chemical properties and geometry of C_{35} in $\text{ASL}^{\text{Arg4}}_{\text{UCU}}$ may distort the positioning of $\text{mnm}^5\text{U}_{34}$, disallowing decoding of AGG. Interestingly, recognition of cognate codon AAA was evident for both unmodified $\text{ASL}^{\text{Lys}}_{\text{UUU}}$ and singly modified $\text{ASL}^{\text{Lys}}_{\text{UUU}}\text{-t}^6\text{A}_{37}$ [10], whereas unmodified ASL^{Arg4} showed no signs of AGA binding. This was particularly surprising considering that the $\text{C}_{35}\bullet\text{G}_2$ base pair is enthalpically preferential to $\text{U}_{35}\bullet\text{A}_2$. Therefore, we can conclude that there are either structural or chemical differences in the anticodon residues that cause a preference for cognate codon binding with a U_{35} .

4.5.2 Biophysical properties suggest a conserved function of loop modifications

Although it is clear that, in terms of wobble decoding, the modifications in ASL^{Arg4} function differently than they do in ASL^{Lys} ; however, the decoding function appears to be linked to the chemical properties of C_{35} rather than the nature of the modifications. Indeed the thermodynamic characteristics upon modification are quite similar to those of the differentially modified ASL^{Lys} . Indeed, we see a decrease in the values of enthalpic, entropic and Gibbs free energy changes with respect to the unmodified ASL (Table 1) which directly mirrors the differences seen in ASL^{Lys} upon modification [10]. Similar to ASL^{Lys} , there is a significant stabilization of the stem in the vicinity of the Ψ modification, which is most likely

caused by the effect of a coordinated water molecule. Also, we see a stabilization of the G₃₉ that appears to be the result of a C₃₂•A₃₈⁺ base pair, which has precedent in human ASL^{Lys3} [4,28]. In the unmodified ASL, this base pair may be transient based on the observed pKa of ~6.8. Interestingly, the significant stabilization of G₃₉ in the triply modified ASL suggests that the pKa of A₃₈ may be shifted higher, allowing for a more stable base pair to form. Also, a slight red-shift seen in the circular dichroism spectra of the triply modified ASL suggests that there may be a difference in the hydrogen bonding properties of this base pair (Figure 3b,c). A slight pKa shift is confirmed by the presence of the unusual upfield shifted A₃₈C2-H2 resonance seen at pH 6.8 in the ¹H-¹³C HSQC spectra of the triply modified ASL. Alternatively, the increased stacking that may occur with the modified, pseudo-heterotricyclic t⁶A₃₇, A₃₈ may be positioned in a more stable position for cross-loop base pairing in a pH-dependent manner. Indeed, both ASLs show an A₃₈H2–U₃₃H1' connectivity indicating the formation of an extended stem.

4.5.4 Modifications do not drive the ASL into a canonical U-turn conformation

The sugar conformations of both unmodified and triply modified ASL^{Arg4} were in disagreement with a U-turn conformation. In the canonical U-turn conformation, all stem and loop residues exhibit a C3'-*endo* sugar conformation. Both ASLs were determined to have predominantly C2'-*endo* sugar puckers for U₃₃, U₃₄ and C₃₅. This slightly mirrors the trend seen for both unmodified ASL^{Lys}_{UUU} and singly modified ASL^{Lys}_{UUU}-t⁶A₃₇, both of which were determined to exhibit C2'-*endo* conformation for U₃₃, U₃₄ and U₃₆ [26]. Here we see a difference in which the position 35 and position 36 sugar puckers between ASL^{Lys} and ASL^{Arg4} are reversed. In both cases, modifications are unable to cause a shift in the sugar pucker; however, a crystal structure of ASL^{Lys} bound in the ribosomal A-site reveals that all residues conform to the C3'-*endo* conformation that is characteristic of the U-turn [23]. Therefore, we suggest a similar mechanism in ASL^{Arg4} in which the loop nucleosides are induced into the C3'-*endo* conformation upon A-site binding. However, this would require a certain amount of flexibility for C₃₅ to switch sugar conformation. Since proper positioning of this residue is required for stabilizing mnm⁵U₃₄ in a geometry that allows for recognition

of G₃ [23], this flexibility may abrogate this function of the position 35 residue.

Besides the C3'-*endo* sugar puckers that are characteristic of a canonical U-turn, the abrupt backbone turn between position 33 and 34 requires that the α dihedral angle be in the *trans* conformation [42], resulting in a signature downfield resonance for 33p34 in ³¹P NMR spectra [43,44]. No such resonances were seen for either the unmodified or the triply modified ASL (Figure 7). It is not uncommon for ASLs to have structures that closely resemble a U-turn motif but lack this signature resonance [4]. Similarly, there have been instances where ASLs that do not contain a U-turn motif are able to efficiently bind to codons in the ribosomal A-site [7,10,26].

Interestingly, this appears to be a common characteristic of *E.coli* arginine ASLs [7]. It is unclear how these particular isoacceptors overcome structural limitations during ribosomal binding; however, similarities in the ASLs suggest that there may be a conserved mechanism for overcoming the non-U-turn solution structure. Both ASL^{Arg1,2} [7] and ASL^{Arg4} lack the pre-structuring that is common to many ASLs [4,8,29]; however, both must conform to the canonical U-turn conformation when bound to the ribosome. The fact that both ASLs contain a cytidine at position 35 that is in the C2'-*endo* conformation may allow for a certain amount of deformability in the loops of these ASLs by inhibiting the more stable stacking interactions that occur between nucleosides that are in the C3'-*endo* orientation. Also, the rare s²C₃₂ modification that is common to these two ASLs may provide insights into this mechanism.

4.5.5 Effects of s²C₃₂ on ASL structure

Since s²C₃₂ is a rare modification and common to both ASL^{Arg1,2} and ASL^{Arg4}, it was hypothesized that there may be a connection between this modification and the uncommon properties that characterize these isoacceptors. In ASL^{Arg1,2}, the s²C₃₂ modification acts negatively by disallowing recognition of the rare CGA codon [7]. Codon-specific ribosome binding assays revealed that the function of s²C₃₂ is neither to abrogate AGG binding of the fully modified ASL nor to allow binding of the unmodified ASL to the cognate AGA codon

(Figure 2a,b). Therefore, a common functional property was not found. Structurally, s^2C_{32} was able to significantly alter the thermal melting properties of the ASL by introducing a low-temperature transition (Figure 3), suggesting that there may be a cross-strand interaction that is stabilized by this modification. A significant thermal dependence of the circular dichroism spectra correlates this result (Figure 3b,c). A large reduction in the maximum ellipticity between 5°C and 20°C suggests that there is a substantial change in the base stacking properties of the ASL between these temperatures. It is unclear whether this is the result of a destabilized extended stem or another yet to be identified property, but full NMR characterization and structure determination is being performed to decipher the conformational properties elicited by this modification.

4.5.5 Conclusions

Based on a full characterization of both the functional decoding and biophysical properties of all three ASL constructs and preliminary NMR investigation, we conclude a novel function of the anticodon domain modifications in the context of $ASL^{Arg^4}_{UCU}$. Biophysically, mnm^5U_{34} and t^6A_{37} produce similar results of decreasing the molecular order while increasing the thermal stability as seen for $ASL^{Lys}_{UUU-mnm^5U_{34};t^6A_{37}}$ [10]. In ASL^{Lys}_{UUU} , this is the result of negating the extended stem; however, triply modified $ASL^{Arg^4}_{UCU}$ still shows strong signs of an extended stem. The extended stem in triply modified $ASL^{Arg^4}_{UCU}$ is stabilized by the elevated pKa of $A_{38}H1$ resulting in a stronger $C_{32}\bullet A_{38}$ base pair. Since we also note a more pronounced stacking interaction between G_{31} and s^2C_{32} and a more stable $s^2C_{32}\bullet A_{38}$ base pair in the singly modified $ASL^{Arg^4}_{UCU-s^2C_{32}}$, we hypothesize that the fully modified ASL will also form this non-canonical base pair which has been shown to be important for codon discrimination [24]. Although ongoing efforts will result in full structure determination of all three ASL constructs, we propose that modification of $ASL^{Arg^4}_{UCU}$ results in a highly stabilized non-canonical $s^2C_{32}\bullet A_{38}$ base pair that enhances the codon discrimination that results from the chemical nature of C_{35} . Additionally, as shown previously [4,10], these modifications may also open the stem-distal loop structure allowing for a more U-turn-like conformation and, in the case of t^6A_{37} , most likely stabilizes the $U_{36}\bullet A_1$

codon•anticodon base pair.

4.6 Materials and methods

4.6.1 Oligonucleotide preparation

Phosphoramidites for s^2C , mnm^5U and t^6A were synthesized as described [7,49], and ASLs and mRNA oligonucleotides were purchased from Dharmacon (Thermo Scientific) and deprotected using standard protocol. RNAs were then dialyzed extensively against 20 mM sodium/potassium phosphate buffer pH 6.8 (10mM Na_2HPO_4 and 10 mM KH_2PO_4) using a 3500 Da cutoff membrane (Pierce). For pH experiments using NMR, adjustment was accomplished using phosphoric acid and sodium hydroxide. Tight-coupled 70S *E.coli* ribosomes for codon binding assays were prepared using sucrose gradient centrifugation as described [50].

4.6.2 Thermal denaturation spectroscopy

Thermal denaturation and renaturation of the ASLs were monitored by UV absorbance at 260 nm with a Cary 100 UV-visible spectrophotometer (Agilent) using Thermal software. All the samples were adjusted to $\sim 0.2 A_{260}$ and the temperature was ramped from 5 to 95°C at 1°C/min at a rate of 1 data point per minute for 5 cycles per experiment. All experiments were performed simultaneously with a control cell containing buffer only, these data were subtracted as the background before analysis. A total of 30 data sets (15 full cycles) were accumulated over 3 different experiments and the first denaturation was excluded from analysis. Thermodynamic properties were determined using the Meltwin v3.5 software and the error was calculated as the standard error of the mean.

4.6.3 Circular dichroism spectroscopy

Circular dichroism spectra were collected on a Jasco J815 spectropolarimeter in a 1 cm pathlength quartz cuvette in which temperature was controlled to either 5°C or 20°C during

data collection. All samples were adjusted to ~ 0.2 A_{260}/mL (ambient temperature) prior to CD analysis. Spectra were baseline corrected using a control containing buffer only. Using simultaneously collected absorbance data to calculate the concentrations of each sample, the spectra were normalized to molar circular dichroic absorbance ($\Delta\epsilon = \theta/32980 \cdot C \cdot L \cdot N$ [51]). Spectra shown are the averaged results of two independent experiments consisting of triplicate data collection.

4.6.4 Codon-specific ribosome A-site binding assays

With little variation, ribosome purification and binding assays were performed according to an established protocol [7]. Using UNAFOLD [52], the following 27-mer mRNAs derived from T4 gp32 [53] were investigated for secondary structure:

- [i] Control mRNA (GCG): 5' – GAAAAGGAGGUAAAAAUGCGCGCACAU – 3'
- [ii] A-site AGA: 5' – GAAAAGGAGGUAAAAAUGAGAGGCACAU – 3'
- [iii] A-site AGG: 5' – GAAAAGGAGGUAAAAAUGAGGGGCACAU – 3'

Heptadecamer ASLs were 5'-³²P-radiolabeled and purified using preparative denaturing 15% polyacrylamide gel electrophoresis. mRNA-programmed ribosomes (250 nM ribosome and 2.5 μM mRNA) were P-site saturated with tRNA^{Met} and incubated for one hour at 37 °C with varying concentrations (0, 0.25, 0.5, 1.0, 1.5, 2.5, 5 μM) of unlabeled ASL spiked with up to 2 kCPM radiolabeled ASL in ribosome binding buffer (50 mM HEPES, pH 7; 30 mM KCl; 70 mM NH₄Cl; 1 mM DTT; 100 μM EDTA; 20 mM MgCl₂ adjusted to pH 7 with 2 M NaOH). Binding reactions were then filtered through a 0.22 μm nitrocellulose filter (Whatman) using a modified Micro-Sample Filtration Manifold (Whatman Schleicher & Schuell Minifold) 96-well dot blot apparatus [54]. A standard curve was generated by spotting known amounts of radiolabeled ASL to a small strip of nitrocellulose filter. Filters were imaged using a Typhoon phosphor imager (GE Healthcare) and radioactive spot density was calculated using ImageQuant TL software (Amersham). Binding constants were calculated using the one-site specific binding function in Prism v3 (Graphpad). An internal

positive control using unmodified yeast ASL^{Phe} binding to polyuridylic acid and non-specific negative controls using a control mRNA with GCG (mRNA [i]) in the A-site position were performed in tandem with every experiment. All binding curves were performed in triplicate in each of three independent experiments. Determination of ribosome activity and usability of mRNAs was accomplished using filter binding assays consisting of only ribosomes and 5'-³²P-radiolabeled mRNAs.

4.6.5 NMR spectroscopy

Complete NMR experiments were performed on unmodified ASL^{Arg4}_{UCU} and triply modified ASL^{Arg4}_{UCU}-mnm⁵U₃₄;t⁶A₃₇;Ψ₄₀. All NMR spectra were collected using ionic and thermal conditions (20mM Na/K phosphate buffer at 293K) commonly used for structure determination of RNA stem loops [25,29,55] on a Bruker 700 MHz instrument equipped with a cryoprobe, triple-resonance ¹H, ¹³C, and ¹⁵N probe and three-axis pulsed field gradient capabilities and a Bruker 400 MHz instrument equipped with ³¹P probe. Data were processed using NMRPIPE [56] and the resulting spectra were analyzed using NMRViewJ (One Moon Scientific Inc). For exchangeable protons, ¹H-¹H NOESY spectra were recorded in 90% H₂O/10% D₂O at a variety of different temperatures (283K, 288K and 293K) and mixing times (50 ms, 100 ms, 200 ms and 400 ms). Non-exchangeable proton spectra were collected at 293K and different mixing times (50 ms, 100 ms, 200 ms and 400 ms). COSY, TOCSY, ¹H-³¹P HETCOR and natural abundance ¹H-¹³C HMQC spectra were recorded at 25°C in 100% in D₂O.

4.7 Acknowledgements

The authors would like to acknowledge the contributions of Dr. C. Stark and Dr. J. Spears for productive conversations and detailed manuscript review. Contributions were also made by Dr. A. Shekhtman and Yu Chen in the form of technical support for NMR instrumentation and computer software, respectively.

4.9 Figures and tables

Table 1. Thermodynamic properties of ASL^{Arg4}_{UCU} constructs derived from thermal melting.

	ΔH (kcal/mol)	ΔS (cal/K* <i>mol</i>)	ΔG (kcal/mol,37°C)	T_m (°C)	%HCT
Unmod	-50.09 ± 0.86	-148.61 ± 2.55	-4.00 ± 0.07	63.93 ± 0.13	11.9 ± 0.1
3x Mod	-41.72 ± 0.93	-123.16 ± 2.77	-3.53 ± 0.08	65.65 ± 0.22	10.2 ± 0.1

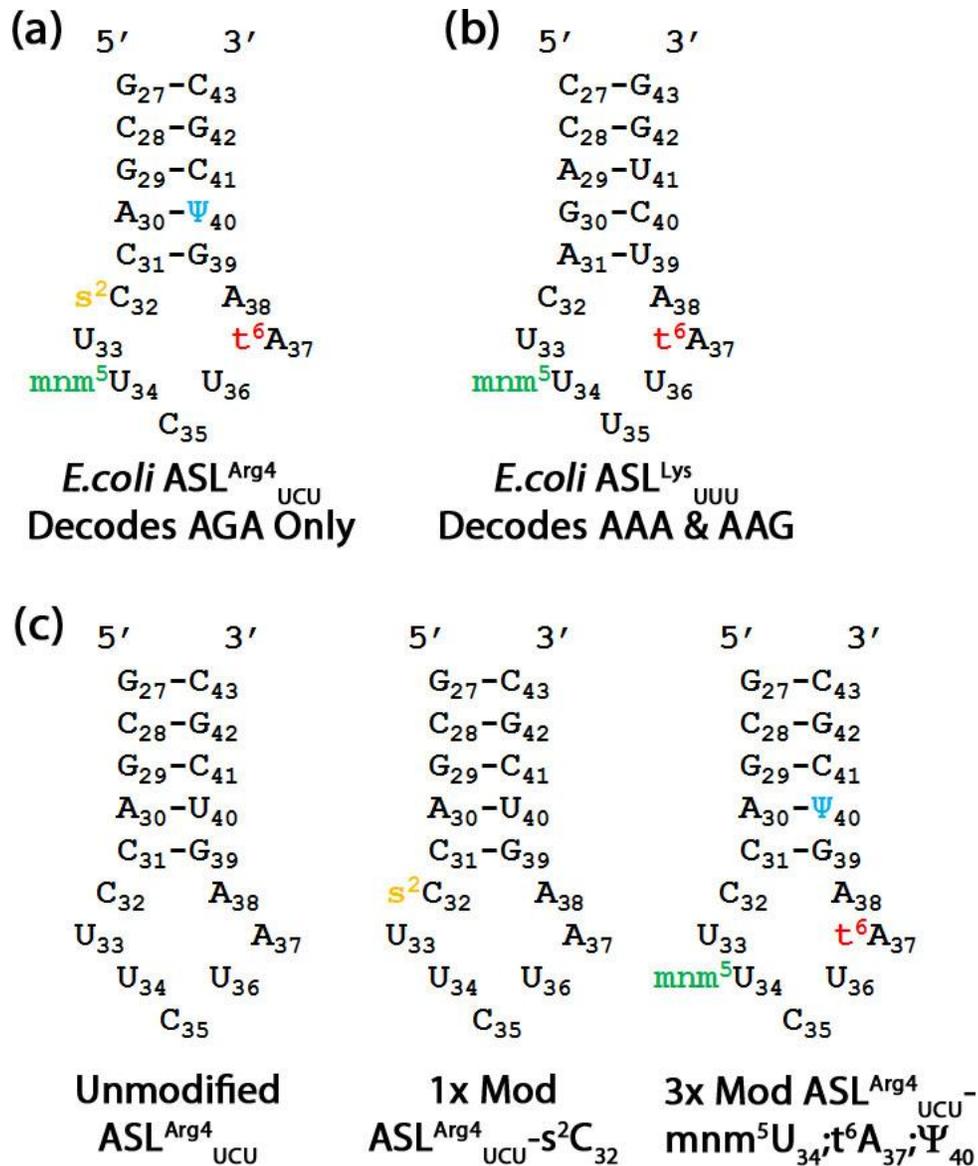

Figure 1. Primary structures of ASL^{Arg4}_{UCU} constructs. (a) The primary sequence of the anticodon domain of wild-type *E.coli* ASL^{Arg4}_{UCU} has four modifications: s²C₃₂ (gold), mnm⁵U₃₄ (green), t⁶A₃₇ (red) and Ψ₄₀ (blue). (b) This sequence can be compared to the hypomodified *E.coli* ASL^{Lys}_{UUU}-mnm⁵U₃₄;t⁶A₃₇, which has a very similar loop sequence but has a very different decoding phenotype [10]. (c) Three ASL constructs were synthesized to determine the function of s²C₃₂, both biophysically and functionally.

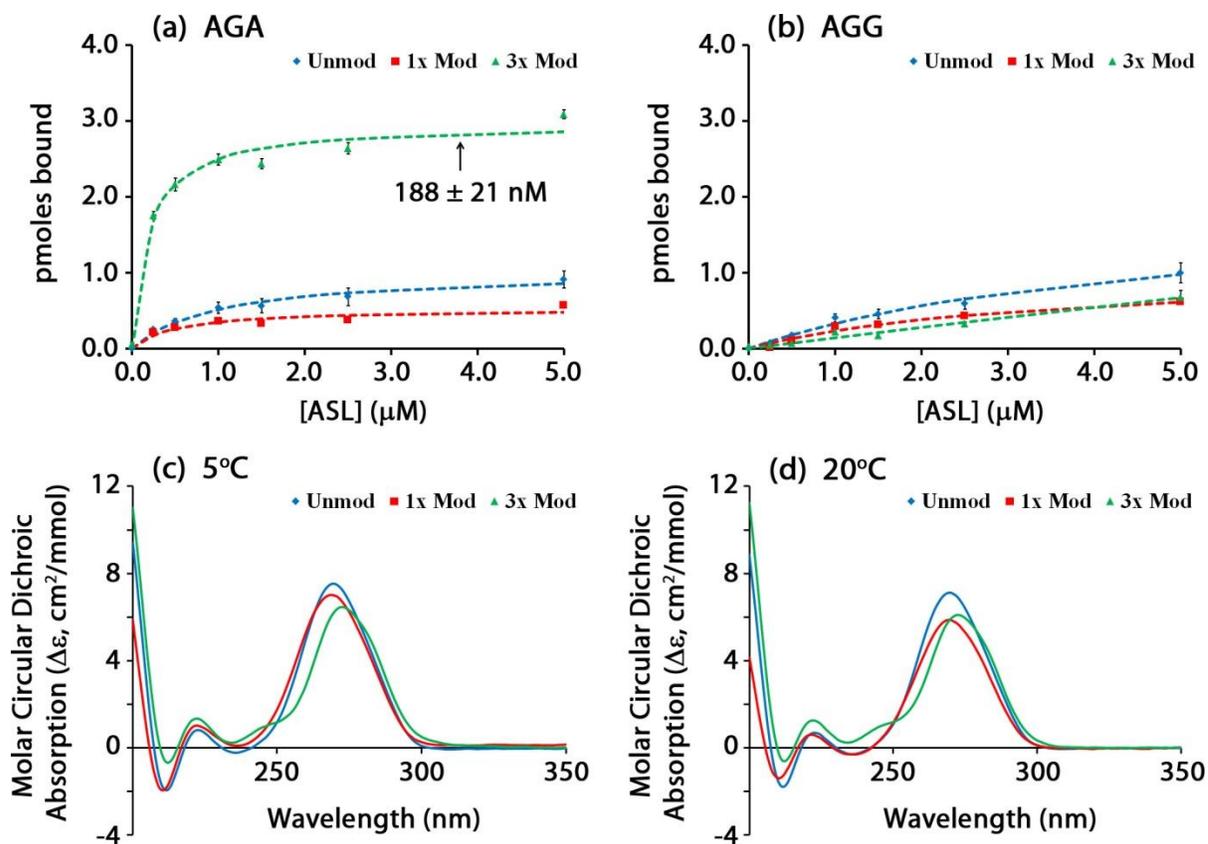

Figure 2. Codon binding assays and circular dichroism spectra. Ribosomal codon binding assays were performed with both (a) AGA and (b) AGG in the A-site, showing that only the triply modified ASL bound efficiently to the AGA codon. Circular dichroism spectra were recorded at (c) 5°C and (d) 20°C to determine both the base stacking properties of each ASL and the thermal stability of the stacking interactions.

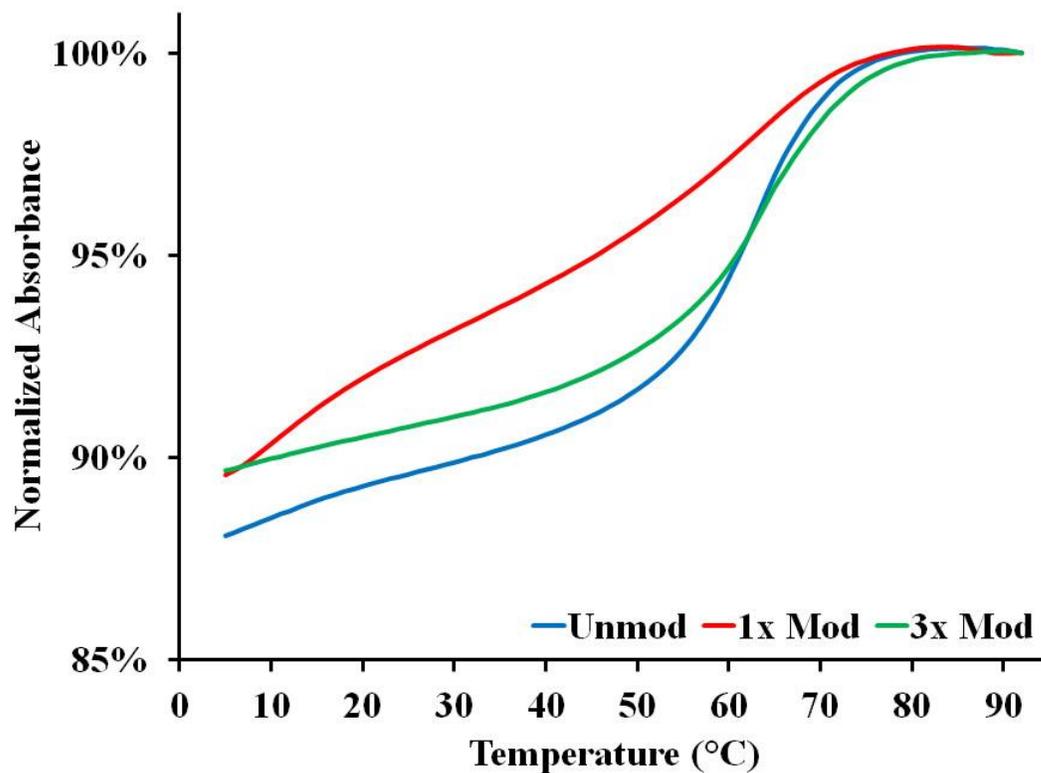

Figure 3. Thermal denaturation and renaturation spectra. Thermal denaturation cycles were monitored by UV absorbance for the three differentially modified ASLs: ASL^{Arg4}_{UCU} (blue), ASL^{Arg4}_{UCU-s²C₃₂} (red) and ASL^{Arg4}_{UCU-mnm⁵U₃₄;t⁶A₃₇; Ψ ₄₀} (green). Curves shown are each the average of 15 full cycles normalized to 100% at the fully denatured state. The arrow indicates a possible intermediate conformation for ASL^{Arg4}_{UCU-s²C₃₂} suggested by an additional change in concavity that did allow for thermodynamic analysis using a two state model as used for the other two curves (Table 1).

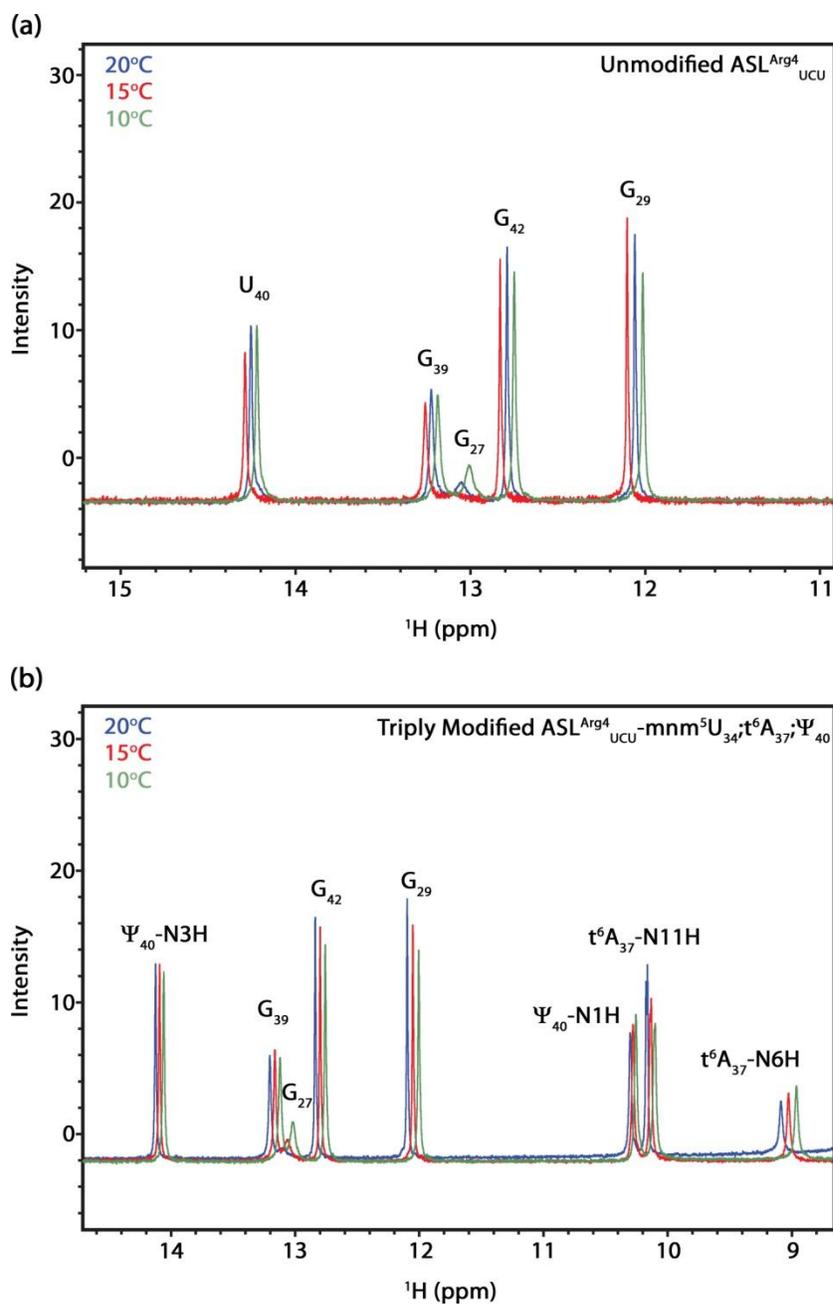

Figure 4. Temperature-dependent 1D imino spectra confirms presence of modifications. (a) Unmodified and (b) triply modified ASLs both showed small variations in the imino region of the NOESY spectra analogous to temperature differences. Also, triply modified ASL^{Arg4} showed additional peaks corresponding to exchangeable protons present in t⁶A₃₇ and Ψ₄₀. Both spectra were recorded at pH 6.8.

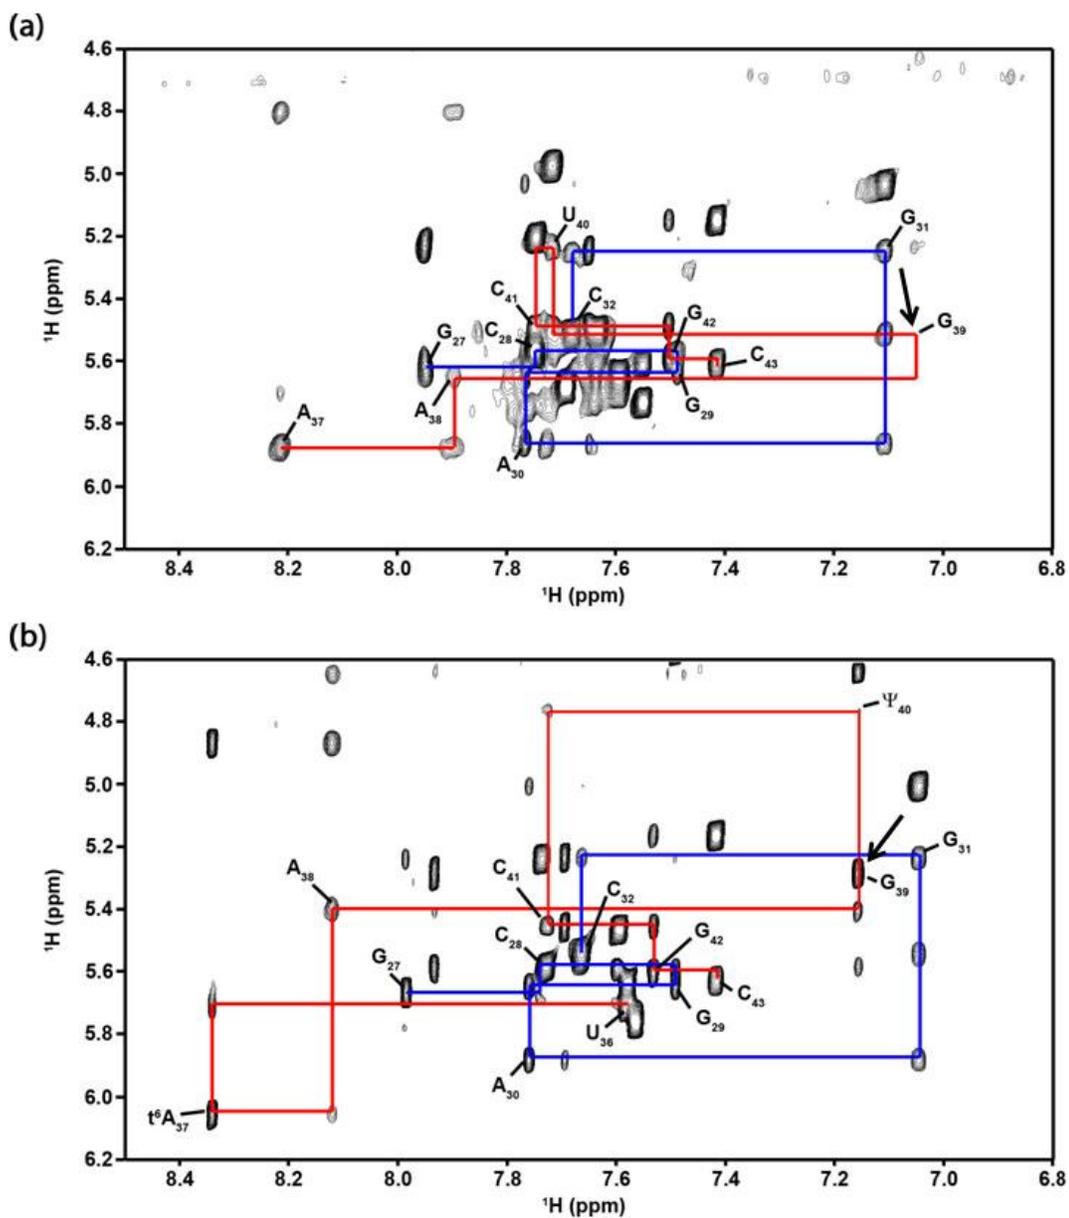

Figure 5. Sequential H1'-aromatic NOE "walk" spectra. A characteristic NOE walk was observed between $G_{27}H_1'$ -H8 and $C_{32}H_1'$ -H6 (blue) and from $A_{37}H_1'$ -H8 to $C_{43}H_1'$ -H6 (red) for unmodified ASL^{Arg4} (a) and triply modified ASL^{Arg4} (b). Arrows indicate the position of resonances $G_{39}H_8$ resonances. Both spectra were recorded at pH 6.8.

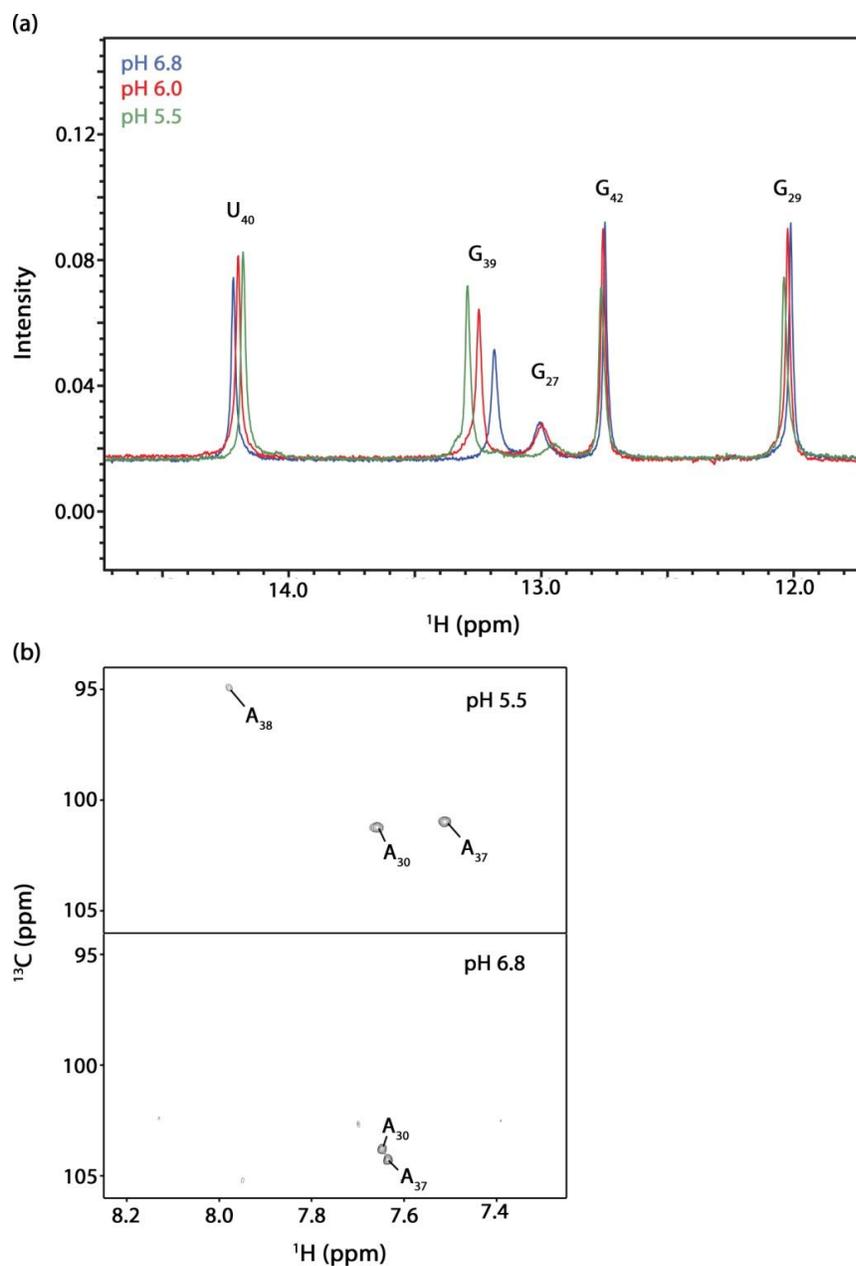

Figure 6. pH-dependent protonation state of unmodified ASL^{Arg4} A₃₈. (a) The imino region of the NOESY spectrum for unmodified ASLArg4 shows a significant peak shift for G₃₉H1 as the pH is decreased from 6.8 (blue) to 6.0 (red) and 5.5 (green). (b) Correspondingly, an unusual shifted A₃₈C2 in the ^1H - ^{13}C HSQC spectrum collected at pH 5.5 indicated the protonation of A₃₈, which could affect the G₃₉H1 resonance.

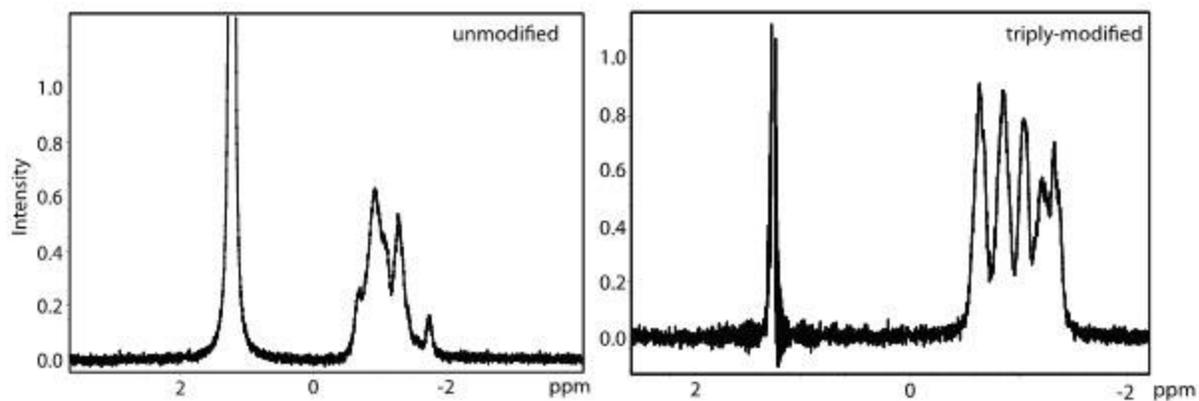

Figure 7. ^{31}P NMR spectra of unmodified and triply-modified ASL^{Arg4} . No downfield shifted resonance, characteristic of a typical U-turn, were observed for both ASLs.

CHAPTER 5. Concluding remarks

5.1 Overcoming problems associated with decoding six-fold degenerate codons

The universal genetic code (see Chapter 1, Figure 1) consists of three amino acids that are coded by six different codons, arginine, leucine and serine. For each set, a single aminoacyl-tRNA synthetase must recognize all isoacceptors. Not only must multiple isoacceptors adopt a uniform conformation for ribosome binding, they must also have the specific structure and chemistry required for specific recognition by the cognate aminoacyl-tRNA synthetase. This becomes a problem with split codon boxes not only because of the ambiguity of the chemistry at the wobble position, but also to allow for different nucleosides at positions 35 and/or 36. For *E.coli* arginyl-tRNAs, the common C₃₅ is used as a strong identity determinant for aminoacylation [1,2]. Based on the crystal structure of the yeast tRNA^{Arg}_{ICG} in complex with its cognate aminoacyl-tRNA synthetase, C₃₅ must be in a position away from other nucleosides and solvent exposed in order to make specific contacts with the protein backbone and sidechains [3]. This requirement for aminoacylation has interesting implications for decoding. First, the anticodon stem and loop domain (ASL) must have significantly more deformability than that of ASLs from other isoacceptors. Second, a significant conformational change must occur between binding to the aminoacyl-tRNA synthetase and adopting the canonical U-turn seen while decoding synonymous codons in the ribosomal A-site [4]. Finally, an induced-fit model for these structural changes requires a specific conformational intermediate to allow for a conformational equilibrium in which the tRNA can be recycled after decoding to be aminoacylated again.

In the studies described herein, we have identified the likely conformational intermediate for ASL^{Arg1}_{ICG} [5]. Despite the unconventional and singular structure of this ASL in different modification states, our data shows a variety modification-dependent of thermodynamic and functional properties. We show, for instance that with only the I₃₄ modification, all three synonymous codons are able to be decoded; however, the addition of either s²C₃₂ or m²A₃₇

completely negates binding to the rare CGA codon. Although the biophysical data indicates that modifications modulate the dynamic properties of the ASL, these properties do not empirically point to a specific mechanism for the codon discrimination. Computational studies presented here describe the environment-dependent, residue-specific flexibility alterations that are imparted in different states of modification. It is clear that the conformational transitions described will require specific residues to have a large conformational space. Interestingly, modifications have typically been seen to induce rigidity into the loop [6,7], which would not be beneficial to a molecule that requires such drastic conformational changes. Therefore, despite having only preliminary computational evidence, we postulate a model in which the state of ASL modification is dynamic and that modifications alter the landscape between the different conformations to both modulate structural transitions and allow for regulation of decoding ability.

Although ASL^{Arg1}_{ICG} has the ability to decode three codons, the remaining three isoacceptors recognize only one codon each. Of these three, ASL^{Arg4}_{UCU} stands out because of its decoding difference with a slightly hypomodified form of ASL^{Lys}_{UUU} despite their nearly identical loop sequence and modifications (See Chapter 4, Figure 1a,b). The fact that the particular geometry of the non-canonical 32•38 base pair participates in regulation of codon discrimination suggested that the s^2C_{32} modification may be responsible for negating wobble decoding [8]. Indeed, s^2C_{32} was shown to inhibit the ability of ASL^{Arg1}_{ICG} to decode the CGA wobble codon [5]. However, in the present study, we have definitively shown that the s^2C_{32} modification is not responsible for negating wobble decoding. Interestingly, analysis of thermodynamic and base stacking properties indicates a similar effect of modifications on the biophysical characteristics of the loop as seen for ASL^{Lys}_{UUU} [9]. A structural analysis shows that modifications participate in allowing cognate decoding through stabilization of the non-canonical 32•38 base pair through modulation of the pKa of A₃₈ and enhancement of base stacking interactions between G₃₁ and s^2C_{32} .

5.2 Anticodon domain modifications as regulators of cellular function

The fact that the modification state of the tRNA^{Arg1}_{ICG} ASL can regulate whether the isoacceptor decodes all three codons or only the two common codons (CGU and CGC) indicates a role for modifications in regulating the function of the tRNA. This would serve three advantageous functions. First, this would counteract the need for two different isoacceptors to decode the common and rare codons. Also, there is not a need for another loop sequence to adopt the same conformations for recognition by both the ribosome and the aminoacyl-tRNA synthetase. Finally, the function of the tRNA, and thus translation of CGA-containing genes, could be regulated by a single modification enzyme rather than a full set of tRNA transcription and maturation factors. The role of modification enzymes as regulators of cellular function has been reported previously in yeast where tRNA methylation is regulated during instances of cellular stress [10]. Here, the expression patterns and activity of the modifications enzymes for s²C₃₂ (TtcA,[11]) and m²A₃₇ (TrmG,[12]) are potential regulators of CGA-containing gene expression at the translational level. Although a thorough examination of genes that include CGA codons has not been determined, genes that are moderately to lowly expressed are enriched with these codons [13]. Taken together, these are very clear indications that the modification state of tRNA^{Arg1}_{ICG} may be dynamically regulated in order to further control expression of CGA-containing mRNAs. A further study using analysis of tRNA modification during different environmental conditions or growth states in addition to analysis of expression patterns and codon bias would successfully test the predictions of these studies.

5.3 Conclusions

In conclusion, our analysis of tRNA^{Arg} ASL modifications has shown an interesting dual role for the rare s²C₃₂ modification. In one instance, it has a clear inhibitory effect on wobble decoding; however, in the context of ASL^{Arg4}_{UCU}, our results indicate that it may enhance cognate codon binding. Indeed, we have also identified a dual role for mnm⁵U₃₄ in

tRNA^{Arg4}_{UCU} and tRNA^{Lys}_{UUU} to either inhibit or allow wobble decoding, respectively. This dual role of ASL modifications underscores the subtlety of modifications and how a single modification can be made to perform different functions depending on the sequence and chemical context of the ASL. In this way, one of the key problems with degeneracy of the genetic code, namely the simultaneous need for structural uniformity and sequence variety in the ASL, can be alleviated through a smaller subset of modification chemistries. Therefore, we propose a model in which the modification state of the ASL is modulated in response to environmental conditions and results in functions that are dependent on the context of the other loop nucleosides and modifications.

APPENDICES

APPENDIX A. 70S ribosome preparation

A.1 Protocol Notes

This protocol is adapted from ribosome preparation protocols performed in the Wollenzien laboratory at North Carolina State University and the Joseph laboratory at the University of California, San Diego. Once flash frozen, these ribosomes are usable indefinitely as long as they are kept at -80°C . The typical aliquot consists of 20 μL for use in codon-specific ribosomal filter binding assays; however, this amount can be safely adjusted for use in other capacities. It is absolutely necessary to use an *Escherichia coli* variant such as MRE600 that has a reduced amount of RNA degradation. Be sure plan ahead; this protocol takes at least two days and, in some cases, can take three days to increase purity or activity.

A.2 Buffer Preparation

Buffers A and B should be prepared fresh for each ribosome purification. After buffer preparation, all buffers should be kept at 4°C or on ice for the duration of the protocol.

100mL Buffer A: 20mM TrisHCl, 20mM MgCl_2 , 200mM NH_4Cl , 4mM 2-mercaptoethanol

1 mL	2 M Tris HCl (pH 7.5)
2 mL	1 M MgCl_2
8 mL	2.5 M NH_4Cl
15.6 μL	2-mercaptoethanol

50mL Buffer B: 20mM TrisHCl, 10mM MgCl_2 , 500mM NH_4Cl , 1mM 2-mercaptoethanol

0.5 mL	2 M Tris HCl (pH 7.5)
0.5 mL	1 M MgCl_2
10 mL	2.5 M NH_4Cl
3.9 μL	2-mercaptoethanol

A.3 Cell Growth and Lysis

1. Weight out ~8g of frozen *E.coli* MRE600 cells.
2. Resuspend cells in 20mL Buffer A.
 - a. **IMPORTANT:** Keep everything on ice!
3. Lyse the cell suspension by sonication.
 - a. Clean the sonicator probe with 95% ethanol and rinse with MQH₂O.
 - b. Sonicate cell suspension for 30 seconds and mix by pipetting up and down.
 - c. Repeat step #4 five more times.
 - d. Clean the sonicator with 95% ethanol and rinse with MQH₂O.

A.4 Sucrose Gradient Purification

1. Aliquot the lysed cell mixture into four ultracentrifuge tubes (balance them carefully!).
2. Centrifuge tubes in a Beckman TI 50.2 rotor.
 - a. Turn on diffusion.
 - b. Turn on vacuum (wait for pressure to go below 500 microns).
 - c. Set the time (20 minutes).
 - d. Set the speed (16k RPM; 30854 x g)
 - e. Set the temperature for 4°C.
 - f. Turn off the brake
 - g. Once the vacuum light is on, push the start button
3. Pour the supernatant into four fresh centrifuge tubes (balance them carefully!).
4. Spin again in ultracentrifuge (follow the pattern in 2a-g) at 30k RPM (108472 x g) for 3 hours at 4°C. The pellet will contain crude ribosomes.
5. Discard the supernatant and invert tubes for 5 minutes to dry at 4°C.
6. Wash each pellet (crude ribosomes) in 1mL Buffer B.

7. Resuspend each pellet in 7mL Buffer B using small (micro) stir bars. Do this slowly and on ice. It should take at least 1 hour.
8. Prepare 50mL of 1.1M sucrose cushion using Buffer B.
9. Load 4mL ribosome suspension onto an 8mL 1.1M sucrose cushion (two samples) in ultracentrifuge tubes. Carefully balance the tubes!
10. Spin again in ultracentrifuge (follow the pattern in 2a-g) at 30k RPM (108472 x g) for 18 hours at 4°C.
11. Wash each pellet with 5mL ice cold Buffer B.
12. Resuspend each pellet in 1mL Buffer B. Do this carefully using the micro stir bars as in step 7 and be sure this step is performed entirely on ice.
13. Make 20µL aliquots and immediately flash freeze them in liquid nitrogen. Store in the -80°C freezer.
14. Once thawed, the ribosome concentration of each aliquot can be determined as follows: $1 A_{260} = 23\text{-}24$ pmoles tight coupled 70S ribosomes (I typically use 23).
15. To improve purity, after step 11, steps 7-11 can be repeated. This is not typically necessary.

APPENDIX B. ³²P 5'-end labeling and urea PAGE purification of RNA

B.1 Protocol Notes

This protocol is set up for samples that are 100 μ M in concentration. The protocol will label 100pmoles of RNA using T4 Polynucleotide Kinase (T4 PNK) from New England Biolabs. You can label more or less by adjusting the labeling recipe accordingly. You should set aside enough time in your schedule for a 1 hour incubation followed by a lengthy polyacrylamide gel electrophoresis (generally around 2.5 hours). Samples may be frozen prior to gel purification; however, yields may be slightly lower. Take note that the labeling reactions can be performed while the gel is being pre-run.

B.2 Labeling Reaction

1. For single labeling reactions, prepare using the following recipe; however, for multiple reactions, a mastermix can be prepared using 10x PNK Buffer, water, and ³²P γ ATP and then subsequently adding specific RNAs and T4 PNK last.

Volume (μ L)	Ingredient
2.5	10x PNK Buffer
15.5	MilliQ H ₂ O
5.0	³² P γ ATP
1.0	PNK Enzyme
1.0	100 μ M RNA

2. Incubate the reactions for 1 hour at 37°C. Longer incubations are possible; however, RNA degradation can occur for extensively long incubations.
3. After labeling, add 15 μ L 2x Urea Loading Buffer (0.05% w/v bromophenol blue, 0.05% w/v xylene cyanol FF, 8M urea, 0.5M EDTA) to each sample.

4. Heat to 90°C for 2 minutes.
5. Place samples in ice until ready to be loaded into the gel.

B.3 Urea Polyacrylamide Gel Electrophoresis (PAGE)

6. Prepare 70mL of 15% polyacrylamide:bis-acrylamide (29:1) in 1x TBE (45mM Tris-borate, 1mM EDTA). NOTE: These solutions are typically prepared in large quantities before performing this protocol. Also, keep this solution cold to ensure that the gel does not polymerize while pouring.
7. Add 70µL TEMED (N,N,N',N'-Tetramethylethylenediamine) and 280µL 10% APS (ammonium persulfate).
8. Pour gel
 - a. Thoroughly clean the glass plates, spacers and comb with ethanol and water.
 - b. Assemble the plates with two spacers along the long sides and secure with large binder clips.
 - c. Place the assembled plates horizontally on top of four P200 pipet tip boxes and elevate the top end (with the notch) to ~15°.
 - d. Using a 25mL glass pipet, add polyacrylamide mixture while tapping the glass to ensure that no bubbles are formed and that the solution traverses the length of the glass plates.
 - e. Remove whatever was used to elevate the glass plates and insert the comb.
 - f. Allow the gel to solidify at room temperature for 30-45 minutes or until fully polymerized.
 - g. Gently remove the comb and assemble the gel apparatus.
 - h. Fill the top reservoir with 1x TBE to ~1cm above the wells and the bottom reservoir to ~1cm above the level of the bottom of the glass plates. Use a syringe filled with running buffer (1x TBE) to ensure that there are no bubbles at the bottom of the glass plates. Also, use this syringe to flush out the wells.
 - i. Pre-run the empty gel at 62 watts for ~1 hour to heat the gel.
9. Load the samples into the desired wells of the gel.

10. Run the gel at 62 watts for ~2.5 hours or until the first dye front reaches ~2cm above the bottom of the gel plates (this may need to be adjusted depending on what size of RNA is being prepared; this preparation assumes a 17-mer).

B.4 Gel Imaging

11. Remove one of the glass plates while keeping the gel on the other plate.
12. Place small (~2mm x 2mm) pieces of nitrocellulose filter around the gel for alignment.
13. Spot radioactive dye (1x Urea Loading Buffer in 50% ethanol spiked with 1uL ³²PγATP; will need to be spiked every so often to account for the radioactive decay) onto the pieces of filter paper for alignment and allow them to dry.
14. Cover the gel and glass plate with saran wrap.
15. Place the gel into the phosphoimaging cassette and close.
16. Let the gel expose for ~5 minutes.
17. Quickly remove the gel from the cassette and close it back up.
18. Scan the cassette with the Typhoon Phosphor Imager in the Molecular Core.
19. Save the image as a *.tif file.
20. Print the image in the original scale (Photoshop allows this).

B.5 Gel Extraction & Precipitation

21. Align the gel on top of the image with the alignment spots.
22. Remove the front portion of the saran wrap so that the gel is accessible.
23. Cut out the gel pieces that correspond to the positions of the ASLs on the printed image.
24. Place the gel pieces into individual 1.5mL microfuge tubes.
25. Pipet 100uL of RNA Elution Buffer (0.5M NH₄OAc, 0.1% SDS, 0.1mM EDTA) into each microfuge tube.
26. Place the tip of a P-1000 pipet tip into a Bunsen burner flame to seal it off.

27. Crush the gel into small pieces using the sealed-off end of the pipet tip.
28. Wash the gel pieces from the pipet tip with 400uL of RNA Elution Buffer into the microfuge tube.
29. Place the microfuge tubes into the rotator and rotate for 2 hours at room temperature.
30. Place the rotator into the cold room and rotate for another 18 hours.
31. Remove microfuge tubes from the rotator and spin them for 5 minutes at max speed on the microcentrifuge.
32. Pipet supernatant into a 2mL Costar filter tube and centrifuge for 2 minutes at max speed. NOTE: If gel pieces still contain more than 50% of the radioactivity (check using Geiger counter), steps 28-29 can be repeated using 100µL RNA Elution Buffer.
33. Remove the filter and add 1mL 100% ethanol and 50uL 3M ammonium acetate.
34. Place samples in the freezer for 1 hour.
35. Remove samples from the freezer and centrifuge in the cold room for 15 minutes and aspirate the supernatant.
36. Allow the tubes to sit out with the lid open until the tubes are dry.
37. Store samples in the plexiglass box in the -20°C freezer.

APPENDIX C. Codon-specific ribosomal A-site filter binding assays and analysis

C.1 Protocol Notes

Prior to performing this protocol, both the control ASL^{Phe} and the ASL of interest (ASL^{Xxx}) should be 5' ³²P-end labeled. Each labeled ASL should be at an activity of 2,000-72,000cpm/ μ L and 2,000-168,000cpm/ μ L for ASL^{Phe} and ASL^{Xxx}, respectively. The assay is set up to be performed in a 96-well PCR plate. This assay will determine the ability of a single ASL to bind to either of two different codons. It contains both an internal positive control (ASL^{Phe}) and a negative control mRNA to be run in parallel within each assay. Also, the data analysis will be performed using a standard curve to obtain the exact number of picomoles bound per data point. This assay will take a significant portion of a day (at least 4 hours) and should be planned and prepared for ahead of time. It is usually good practice to start the incubators at least one hour prior to beginning the assay. Also, prior to performing this assay, the mRNAs and ribosome activity should be tested by performing this assay with labeled mRNAs and not using ASL or tRNA^{fMet}.

C.2 Preparation of Mastermixes

Mastermixes should be prepared according to the spreadsheet that has been set up to calculate amounts of each ingredient and each sheet should be labeled with the correct date and purpose for easy input into a lab notebook and to keep a correct digital copy (Figure 1a). In general, all ASLs, mRNAs and tRNA^{fMet} should be prepared to a concentration of 100uM; however, these values can be altered in the setup area of the protocol (Figure 1b). Enter the correct values for the radioactivity into the CPM column of the setup table (Figure 1b). Also, ensure that the labels are automatically changed accordingly (Figure 1c).

1. Prepare 5x RB buffer (ideally, this should be prepared in advance; Figure 2).
2. Turn on the water bath to 42°C and the heat block to 80°C.
3. Remove one ribosome aliquot from the -80°C freezer and measure the absorbance at A₂₆₀ of 1 μ L in 1000 μ L total aqueous volume.

4. Multiply the $OD_{260}/\mu\text{L}$ by 23 pmoles/ OD_{260} to obtain to obtain the ribosome concentration in μM . Enter this value into the setup table (Figure 1b).
5. Prepare mastermixes on ice.
 - a. For the ASL mastermixes, add all ingredients except for 5x buffer, incubate at 80°C for 2 minutes, allow to cool to room temperature and place on ice prior to addition of 5x buffer.
 - b. All other mastermixes should be prepared by adding water and 5x buffer prior to the remaining ingredient.
 - c. Label PolyU, control mRNA, mRNA #1 and mRNA #2 with “A”, “B”, “C” and “D”, respectively. These will serve as the basis for the working mixes.

C.3 Assay Protocol

6. Incubate ribosome, $tRNA^{fMet}$ and ASL mastermixes at 42°C for 10 minutes.
7. Slow cool ribosome, $tRNA^{fMet}$ and ASL mastermixes to 37°C (usually takes 25-30 minutes).
 - a. While these mastermixes are cooling, add the noted amounts of 1x RB buffer to the noted wells of a PCR plate (Figure 3). From here on, keep the PCR plate on ice at all times unless otherwise specified.
 - b. Place the PCR plate on ice when finished.
 - c. Cut a piece of nitrocellulose filter paper to fit onto a filter binding apparatus. Place into a pipet tip lid and soak with 1x RB buffer.
 - d. Place the filter paper, P200 tip box and filter binding apparatus into the refrigerator to equilibrate to 4°C .
8. Incubate ribosome, $tRNA^{fMet}$ and ASL mastermixes at 37°C for 10 minutes.
9. Prepare the initial working mixes.
 - a. Add $115\mu\text{L}$ ribosome mastermix to “Tube A” (PolyU)
 - b. Add $115\mu\text{L}$ ribosome mastermix to “Tube B” (Control mRNA)
 - c. Add $115\mu\text{L}$ ribosome mastermix to “Tube C” (mRNA #1)
 - d. Add $115\mu\text{L}$ ribosome mastermix to “Tube D” (mRNA #2)

- e. Incubate these mixes for 15 minutes at 37°C.
10. While working mixes are incubating, prepare ASL mastermix dilutions and add them to the PCR plate.
 - a. Add 13µL of ASL^{Phe} mastermix to 117µL 1x RB buffer.
 - b. Add 18µL of ASL^{Xxx} mastermix to 162µL 1x RB buffer.
 - c. Add the ASL mastermixes to the PCR plate (Figure 4).
11. Add 115µL tRNA^{fMet} mastermix to working mixes B-D and 115µL of 1x RB buffer to working mix A. Incubate these working mixes at 37°C for 15 minutes.
12. Add 15µL of the noted working mix to the noted PCR plate wells (Figure 5). Pipet up and down to mix.
13. Incubate the PCR plate at 37°C for 60 minutes.
14. Incubate the PCR plate on ice for 30 minutes.
15. Place the equilibrated filter on the filter binding apparatus and attach a slow vacuum.
16. Wash the filter with 150µL ice cold 1x RB buffer in each well twice.
17. Add 100µL ice cold 1x RB buffer to each well of the PCR plate and immediately pipet the contents onto the filter binding apparatus.
18. Wash 2x with 150µL ice cold 1x RB buffer.
19. Remove the filter from the apparatus (careful not to touch any of the wells) and let sit on KimWipes to dry.
20. Spot 0.5, 1.0, 1.5, 2.0 and 2.5µL of ASL mastermix dilutions in triplicate onto a separate piece of filter paper (standard curve).
21. When dry, wrap both filters in Saran wrap and expose to a phosphor screen for 45 minutes.
22. Remove the filters from the screen and scan using the Typhoon Phosphor Imager (GE Healthcare) using the setting for highest resolution.

C.4 Data Analysis

23. Use ImageQuant TL to quantify each spot and export the data into an MS Excel sheet.
24. Use the standard curve to calculate pmoles bound and subtract the negative control.

25. Use Graphpad Prism to calculate the binding constants using the One-Site Specific binding equation.

APPENDIX D. Standard molecular dynamics simulations of ASLs using AMBER11

D.1 Protocol Notes

This protocol is designed for the explicit solvent simulation of a heptadecamer (17mer) ASL neutralized with Na⁺ ions, minimized, equilibrated for 120ps and simulated under production conditions for a total of 6ns. The protocol can be adjusted to allow for any number of different types of simulations. The main protocol described uses only the SANDER module in AMBER11 using AmberTools1.5 for setup; however, I have appended a section at the end that makes use of GPGPU acceleration using PMEMD. Prior to attempting this protocol, it is advised that the user familiarize themselves with the use of Linux/Unix operating systems. Also, the user should meet with members of the Research IT department at the University at Albany or The RNA Institute to discuss usage of the HPC cluster or GPGPU workstations/cluster, respectively. The protocols herein can be extrapolated to perform other types of simulation either with AMBER11, future implementations of AMBER, GROMACS or NAMD. All text for input files, commands and scripts are denoted by the use of **Courier New** (monotype) bold font and are boxed. Commands will be denoted by the use of either a \$ for command line or > for *leap* commands (do not actually include the \$ or > in the command). All of the simulations presented here can be manipulated by changing variables in the input files. Please consult the AmberTools1.5 or AMBER11 manual prior to making adjustments to your simulations.

D.2 Preparation of Parameter Files

Prior to generation of input files, two things will be necessary: (1) a pdb file containing only your molecule (this can be edited to introduce mutations or modifications) and (2) the proper force field parameter files (only necessary for modified residues). The input files will be created using either the *tleap* or *xleap* modules from AmberTools1.5 for either command line or graphical interfaces, respectively. This protocol will make use of *xleap* to allow for investigation of the structure for anomalies.

1. Plan out your simulations and create organized folders accordingly.
2. Navigate to the path of your pdb file.
3. Execute *xleap* (this command assumes that `$AMBERHOME` is defined and `$AMBERHOME/bin` is added to your `PATH`).

```
$xleap -s -f $AMBERHOME/dat/leap/cmd/leaprc.ff99SB
```

4. Inside of the GUI, use the following commands.
 - a. Load any modification parameters that are necessary (an example for s^2C is shown).

```
>loadamberprep 2SC.prepin  
>loadamberparams 2SC.frcmod
```

- b. Load the pdb file (ensure that the correct atoms are added, if not correct, you may need to go back and edit the pdb file to be more leap-friendly).

```
>model = loadpdb "XXX.pdb"
```

- c. Check the structure for problems including improper or missing bonds, unbounded atoms or distorted structure.

```
>edit model
```

- d. Neutralize the ASL with Na^+ ions.

```
>addions model Na+ 0
```

- e. Solvate the molecule with explicit TIP3P water molecules in a truncated octahedral water box (the example is for a 10.0\AA cutoff).

```
>solvateoct model TIP3PBOX 10.0
```

- f. Save the prmtop and inpcrd files.

```
>saveamberparm model XXX.prmtop XXX.inpcrd
```

D.3 First Minimization

During the first minimization, we are mostly interested in allowing the solvent molecules to minimize. We do this mostly because the solvent molecules were arbitrarily placed by *xleap* and are not in their lowest energy state. To accomplish this, the solute is held fixed under a very high restraint force during minimization.

5. Create the following input file for the first minimization step and give it a name (example: ACG_min1.in).

- a. Input file (example: ACG_min1.in)

```
ACG heptadecamer: initial minimisation with solvent + Na ions
&cntrl
  imin   = 1,
  maxcyc = 1000,
  ncyc   = 500,
  ntb    = 1,
  ntr    = 1,
  cut    = 10
/
Hold the RNA fixed
500.0
RES 1 17
END
END
```

- b. Parameter definitions

```
imin=1           # 1 = minimisation turned on.
maxcyc=1000     # Total number of steps. 1000 as default.
ncyc=500        # Steps of steepest descent. 500 as default.
ntb=1           # 1 = constant volume periodic boundaries.
ntr=1           # 1 = Use position restraints based on GROUP.
cut=10          # Angstrom cutoff.
Held RNA fixed  # Type of molecule. RNA as default.
Force Const. 500.0 # Force constant. 500 kcal/mol/A^2 as default.
Fixed Res 1-17   # Total number of residues to restrain.
```

6. Execute the first minimization using the following command.

- a. For serial minimization:

```
$sander -O -i ACG_min1.in -o ACG_min1.out -p ACG.prmtop -c
ACG.inpcrd -r ACG_min1.rst -ref ACG.inpcrd
```

- b. For parallel minimization on the cluster (the `-N` flag denotes the number of nodes, `-n 8` denotes the number of processors, `-J` is for the name of the job on the cluster, `-p` to denote that a batch job is being used and `--wrap` is for the execution command) **NOTE:** The `-N` and `-n` flags can be adjusted. For instance minimizations do not require 8 processors to be efficient, 2 or 4 should be plenty.

```
$sbatch -N 1 -n 8 -J ACG -p batch --wrap="mpirun -np 8 sander.MPI -
O -i ACG_min1.in -o ACG_min1.out -p ACG.prmtop -c ACG.inpcrd -r
ACG_min1.rst -ref ACG.inpcrd"
```

- c. Parallel simulations can be monitored using the command: `$squeue`

D.4 Second Minimization

Following minimization of the solvent, it is important to allow for minimization of the entire system. To accomplish this, the solute is now released from any restraints and the entire system is allowed to minimize. During this step, a very large number of cycles are used (15,000) to ensure full minimization of the system. This is probably overkill; however, not fully minimizing the system can result in simulation artifacts later. Here, where very little computational resources are required per cycle, is the best place to use excessive cycles.]

7. Once the first minimization is finished, create the input file for the second minimization step and give it a name (example: `ACG_min2.in`).
- a. Input file (example `ACG_min2.in`)

```
ACG heptadecamer: initial minimisation, whole system
&cntrl
  imin   = 1,
  maxcyc = 15000,
  ncyc   = 1000,
  ntb    = 1,
  ntr    = 0,
  cut    = 10
/
```

- b. Parameter definitions

```
imin=1          # 1 = minimisation turned on.
maxcyc=15000    # Total number of steps. 15000 as default.
ncyc=1000       # Steps of steepest descent. 1000 as default.
ntb=1           # 1 = Constant volume periodic boundaries.
ntr=0           # 0 = Do not use position restraints.
cut=10          # Use the same cutoff
```

8. Execute the second minimization using the following command.

a. For serial minimization:

```
$sander -O -i ACG_min2.in -o ACG_min2.out -p ACG.prmtop -c
ACG_min1.rst -r ACG_min2.rst
```

b. For parallel minimization on the cluster (the `-N` flag denotes the number of nodes, `-n 8` denotes the number of processors, `-J` is for the name of the job on the cluster, `-p` to denote that a batch job is being used and `--wrap` is for the execution command) **NOTE:** The `-N` and `-n` flags can be adjusted. For instance minimizations do not require 8 processors to be efficient, 2 or 4 should be plenty.

```
$sbatch -N 1 -n 8 -J ACG -p batch --wrap="mpirun -np 8 sander.MPI -
O -i ACG_min2.in -o ACG_min2.out -p ACG.prmtop -c
ACG_min1.rst.inpcrd -r ACG_min2.rst"
```

c. Parallel simulations can be monitored using the command: `$squeue`

D.5 First Equilibration

During the first equilibration, it is necessary to allow the system to slowly heat up from 0-300k. During this time, it is possible for the system to undergo very drastic, unwanted structural transitions. Therefore, it is very important to ensure that the solute (ASL) is held fixed with a small restraint force.

9. Once minimizations are complete, create the input file for the first equilibration step and give it a name (example: ACG_equ1.in).

a. Input file (example ACG_equ1.in)

```

ACG heptadecamer: 20.000 picoseconds MD with restraint on RNA
&cntrl
  imin      = 0,
  irest     = 0,
  ntx       = 1,
  ntb       = 1,
  ntr       = 1,
  cut       = 10,
  ntc       = 2,
  ntf       = 2,
  tempi      = 0.0,
  temp0     = 300.0,
  ntt       = 3,
  ig        = -1,
  gamma_ln  = 1.0,
  nstlim    = 10000,
  dt        = 0.002,
  ntp       = 100,
  ntwx      = 100,
  ntwr      = 1000,
/
Hold the RNA fixed with weak restraints
10.0
RES 1 17
END
END

```

b. Parameter definitions

```

imin=0          # 0 = minimisation turned off.
irest=0         # 0 = restart MD using no initial vel info.
ntx=1           # 1 = no initial velocity info. Use inpcrd.
ntb=1           # 1 = use constant volume periodic boundaries.
cut=10          # Use the same cutoff.
ntr=1           # 1 = use position restraints based on GROUP.
ntc=2           # 2 = use SHAKE for all H-containing bonds.
ntf=2           # 2 = use SHAKE for all H-containing bonds.
tempi=0.0      # Initial temperature. 0.0k as default.
temp0=300.0    # Final temperature. 300.0k as default.
ntt=3           # Use Langevin dynamics to control temp.
ig=-1          # -1 = use a random seed for initial traj.
gamma_ln=1.0   # Use 1.0ps^-1 collision frequency.
nstlim=10000   # Total number of md steps. 10000 as default.
dt=0.002       # Time step. 2fs as default (0.002ps).
ntp=100        # Step interval to write to output file.
ntwx=100       # Step interval to write to traj file.
ntwr=1000     # Step interval to write to restart file.
type=$m1_type  # Use the same molecule type.
fconst=10.0    # Force constant. 10 kcal/mol/A^2 as default.
residues=1-17  # Use the same number of residues.

```

10. Execute the first equilibration using the following command.

a. For serial equilibration:

```
$ sander -O -i ACG_equ1.in -o ACG_equ1.out -p ACG.prmtop -c ACG_min2.rst -r ACG_equ1.rst -x ACG_equ1.mdcrd -ref ACG_min2.rst
```

b. For parallel equilibration on the cluster (the `-N` flag denotes the number of nodes, `-n 8` denotes the number of processors, `-J` is for the name of the job on the cluster, `-p` to denote that a batch job is being used and `--wrap` is for the execution command) **NOTE:** The `-N` and `-n` flags can be adjusted. For instance the first equilibration does not require 8 processors to be efficient, 4 should be plenty.

```
$sbatch -N 1 -n 8 -J ACG -p batch --wrap="mpirun -np 8 sander.MPI -O -i ACG_equ1.in -o ACG_equ1.out -p ACG.prmtop -c ACG_min2.rst -r ACG_equ1.rst -x ACG_equ1.mdcrd -ref ACG_min2.rst"
```

c. Parallel simulations can be monitored using the command: `$squeue`

D.6 Second Equilibration

The second equilibration is performed under production conditions in order to allow for the system to have time to fully equilibrate at 300k.

11. Once the first equilibration is complete, create the input file for the second equilibration step and give it a name (example: ACG_equ2.in).

a. Input file (example ACG_equ2.in)

```
ACG heptadecamer: 100.000 picoseconds MD with no restraints, whole system
&cntrl
  imin      = 0,
  irest     = 1,
  ntx       = 5,
  ntb       = 2,
```

```

pres0 = 1.0,
ntp = 1,
taup = 2.0
ntr = 0,
cut = 10,
ntf = 2,
ntc = 2,
tempi = 300.0,
temp0 = 300.0,
ntt = 3,
gamma_ln = 1.0,
nstlim = 50000,
dt = 0.002,
ntpr = 100,
ntwx = 100,
ntwr = 1000
/

```

b. Parameter definitions

```

imin=0          # 0 = minimisation turned off.
irest=1         # 1 = restart MD using previous vel info.
ntx=5           # 5 = use initial vel and box info from rst file.
ntb=2           # 2 = use constant pressure periodic boundaries.
pres0=1.0       # Constant pressure value in atm. 1.0 as default.
ntp=1           # 1 = isotropic pos. scaling to maintain pressure.
taup=2.0        # Relaxation time in ps. 2.0 as default.
cut=10          # Use the same cutoff.
ntr=0           # 0 = do not use position restraints.
ntc=2           # 2 = use SHAKE for all H-containing bonds.
ntf=2           # 2 = use SHAKE for all H-containing bonds.
tempi=300.0     # Initial temperature. 300.0k as default.
temp0=300.0     # Final temperature. 300.0k as default.
ntt=3           # Use Langevin dynamics to control temp.
gamma_ln=1.0    # Use 1.0ps^-1 collision frequency.
nstlim=50000    # Total number of md steps. 50000 as default.
dt=0.002        # Time step. 2fs as default (0.002ps).
ntpr=100        # Step interval to write to output file.
ntwx=100        # Step interval to write to traj file.
ntwr=1000       # Step interval to write to restart file.

```

12. Execute the second equilibration using the following command.

c. For serial equilibration:

```

$ sander -O -i ACG_equ2.in -o ACG_equ2.out -p ACG.prmtop -c
ACG_equ1.rst -r ACG_equ2.rst -x ACG_equ2.mdcrd

```

- d. For parallel equilibration on the cluster (the `-N` flag denotes the number of nodes, `-n 8` denotes the number of processors, `-J` is for the name of the job on the cluster, `-p` to denote that a batch job is being used and `--wrap` is for the execution command) **NOTE:** The `-N` and `-n` flags can be adjusted. For instance the second equilibration will require 4-8 processors to be efficient.

```
$sbatch -N 1 -n 8 -J ACG -p batch --wrap="mpirun -np 8 sander.MPI -
O -i ACG_equ2.in -o ACG_equ2.out -p ACG.prmtop -c ACG_equ1.rst -r
ACG_equ2.rst -x ACG_equ2.mdcrd"
```

- e. Parallel simulations can be monitored using the command: `$squeue`

D.7 CPU-based Production Simulations using SANDER.MPI

Production simulations should be run using the same parameters as those used for the equilibration; however, they are typically on a larger scale. It is typically advisable to use the first 1ns of production simulation as an extended equilibration. ASLs have typically been simulated for ~5ns; however, as computational resources become more available, this number should grow. Please plan your simulations according to accepted practices described in the literature.

13. Once both minimizations and equilibrations are complete, create the input file for the production step and give it a name (example: `ACG_pro1.in`) **NOTE:** The example input file created below is for a 1ns simulation. You can change the length of the simulation by adjusting the `nstlim` parameter.

- f. Input file (example `ACG_pro1.in`)

```
ACG heptadecamer: 1 nanoseconds production MD with no restraints,
whole system
&cntrl
  imin      = 0,
  ig        = -1,
  irest     = 1,
  ntx       = 5,
  ntb       = 2,
  pres0     = 1.0,
```

```

ntp      = 1,
taup     = 2.0
ntr      = 0,
cut      = 10,
ntf      = 2,
ntc      = 2,
tempi    = 300.0,
temp0    = 300.0,
ntt      = 3,
gamma_ln = 1.0,
nstlim   = 500000,
dt       = 0.002,
ntpr     = 100,
ntwx     = 100,
ntwr     = 1000

```

/

g. Parameter definitions

```

imin=0      # 0 = minimisation turned off.
ig=-1       # -1 = use a random seed for initial traj.
irest=1     # 1 = restart MD using previous vel info.
ntx=5       # 5 = use initial vel and box info from rst file.
ntb=2       # 2 = use constant pressure periodic boundaries.
pres0=1.0   # Constant pressure value in atm. 1.0 as default.
ntp=1       # 1 = isotropic pos. scaling to maintain pressure.
taup=2.0    # Relaxation time in ps. 2.0 as default.
cut=10      # Use the same cutoff.
ntr=0       # 0 = do not use position restraints.
ntc=2       # 2 = use SHAKE for all H-containing bonds.
ntf=2       # 2 = use SHAKE for all H-containing bonds.
tempi=300.0 # Initial temperature. 300.0k as default.
temp0=300.0 # Final temperature. 300.0k as default.
ntt=3       # Use Langevin dynamics to control temp.
gamma_ln=1.0 # Use 1.0ps^-1 collision frequency.
nstlim=50000 # Total number of md steps. 50000 as default.
dt=0.002    # Time step. 2fs as default (0.002ps).
ntpr=100    # Step interval to write to output file.
ntwx=100    # Step interval to write to traj file.
ntwr=1000   # Step interval to write to restart file.

```

14. Execute production simulation using the following command.

h. For serial production simulation:

```

$ sander -O -i ACG_equ2.in -o ACG_equ2.out -p ACG.prmtop -c
ACG_equ1.rst -r ACG_equ2.rst -x ACG_equ2.mdcrd

```

- i. For parallel production simulation on the cluster (the `-N` flag denotes the number of nodes, `-n 8` denotes the number of processors, `-J` is for the name of the job on the cluster, `-p` to denote that a batch job is being used and `--wrap` is for the execution command) **NOTE:** The `-N` and `-n` flags can be adjusted. For instance the production simulations will require at least 8 processors to be efficient.

```
$sbatch -N 1 -n 8 -J ACG -p batch --wrap="mpirun -np 8 sander.MPI -
O -i ACG_equ2.in -o ACG_equ2.out -p ACG.prmtop -c ACG_equ1.rst -r
ACG_equ2.rst -x ACG_equ2.mdcrd"
```

- j. Parallel simulations can be monitored using the command: `$squeue`

D.7 GPGPU-based Production Simulations using PMEMD.CUDA

GPGPU-based production simulations using PMEMD should be run using the same parameters as those used for the CPU-based simulation; however, GPGPU simulations are designed and will scale better with larger systems and longer time scales. It is typically advisable to use the first 1ns of production simulation as an extended equilibration even when using PMEMD. You should be able to improve your simulation speed for anything >12k atoms (in explicit solvent).

15. Once both minimizations and equilibrations are complete, create the input file for the production step and give it a name (example: `ACG_pro1.in`) **NOTE:** The example input file created below is for a 50ns simulation. You can change the length of the simulation by adjusting the `nstlim` parameter.

- k. Input file (example `ACG_pro1.in`)

```
ACG heptadecamer: 1 nanoseconds production MD with no restraints,
whole system
&cntrl
  imin      = 0,
  ig        = -1,
  irest     = 1,
  ntx       = 5,
```

```

ntb      = 2,
pres0    = 1.0,
ntp      = 1,
taup     = 2.0
ntr      = 0,
cut      = 10,
ntf      = 2,
ntc      = 2,
temp_i   = 300.0,
temp_0   = 300.0,
ntt      = 3,
gamma_ln = 1.0,
nstlim   = 25000000,
dt       = 0.002,
ntpr     = 100,
ntwx     = 100,
ntwr     = 1000
/

```

1. Parameter definitions

```

imin=0      # 0 = minimisation turned off.
ig=-1      # -1 = use a random seed for initial traj.
irest=1     # 1 = restart MD using previous vel info.
ntx=5      # 5 = use initial vel and box info from rst file.
ntb=2      # 2 = use constant pressure periodic boundaries.
pres0=1.0  # Constant pressure value in atm. 1.0 as default.
ntp=1      # 1 = isotropic pos. scaling to maintain pressure.
taup=2.0   # Relaxation time in ps. 2.0 as default.
cut=10     # Use the same cutoff.
ntr=0      # 0 = do not use position restraints.
ntc=2      # 2 = use SHAKE for all H-containing bonds.
ntf=2      # 2 = use SHAKE for all H-containing bonds.
temp_i=300.0 # Initial temperature. 300.0k as default.
temp_0=300.0 # Final temperature. 300.0k as default.
ntt=3      # Use Langevin dynamics to control temp.
gamma_ln=1.0 # Use 1.0ps^-1 collision frequency.
nstlim=25000000 # Total number of md steps. 25000000 as default.
dt=0.002   # Time step. 2fs as default (0.002ps).
ntpr=100   # Step interval to write to output file.
ntwx=100   # Step interval to write to traj file.
ntwr=1000  # Step interval to write to restart file.

```

16. Currently, there is only the capability of using a single GPGPU (Tesla C2075) at a time on a single workstation (tesla1 or tesla2). Execute production simulation using the following command.

m. For serial production simulation:

```
$ pmemd.cuda -O -i ACG_equ2.in -o ACG_equ2.out -p ACG.prmtop -c  
ACG_equ1.rst -r ACG_equ2.rst -x ACG_equ2.mdcrd
```

D.8 Data Analysis

Analysis scripts will vary depending on what you are trying to see in your simulations. In this section, I have included an example analysis script that calculates the backbone, mass weighted, non-weighted and heavy atom RMSD vs time. Also, the overall molecular and per residue RMSF and B-factors are calculated. Finally, the script has one example each of how to calculate a dihedral angle, sugar pucker and atomic distance vs time. The script then creates an input file for the creation of a pdb file that contains an ensemble of snapshot structures taken over the course of 5ns at intervals of 10ps. The script then invokes the *ptraj* module from AmberTools1.5 to execute the input files. Last, the *process_mdout.perl* script creates detailed tables of the contents of the sander output files. Of course, more detailed analyses can be performed by simply adding more parameters to the input files or by determining specific properties to examine by investigating the resulting pdb file.

```

APPENDIX E. Targeted molecular dynamics simulations of ASLs using AMBER11

E.1 Protocol Notes

Targeted molecular dynamics is a method of biasing a system toward a particular conformation. In doing this, it is possible to determine hypothetical conformational pathways between both small and large conformational changes. The software does this by introducing an energy penalty that is based on the RMSD between the current conformation and a reference structure (the one that you are biasing the system to adopt). There are a few ways to accomplish this task, one is by simply setting the target RMSD to zero and optimizing the force factor. While this works very well for small conformational changes, there is a drawback that the force on your molecule will not be constant throughout the simulation. Also, if you are attempting to compare different systems, you may find that some systems have different optimum force constants, rendering your comparison dependent on an outside bias. Another way to accomplish this is to use a slightly larger force constant, but with enough leeway to allow for some sampling occur at each time point. While doing this, you can linearly reduce the target RMSD over time. This will keep the force more constant, will alleviate the possibility of getting stuck in energy wells and you can use the same settings for multiple systems and adequately compare them. The force constant should still be optimized to allow for proper conformational sampling during the simulation.

E.2 Input File Preparation

A key necessity of this type of simulation is that the total number of atoms in the starting structure and the reference structure (including solvent atoms) must be exactly the same. They do not all need to be included in the mask, but they should be the same nonetheless. Also, both structures should be fully minimized prior to performing targeted molecular dynamics. Typically, I will perform minimization, equilibration and an initial 1ns of production simulation and use the resulting structure as the starting point for targeted molecular dynamics (See Appendix D2-D7). Since the starting structure is the base structure,

I typically use the number of atoms in this structure and create the input files for the reference structure to conform to this exact number of atoms.

1. Plan out your simulations and create organized folders accordingly.
2. Create input files, minimize, equilibrate and run the first 1ns of production simulation based on the protocol for standard molecular dynamics simulation (Appendix D2-D7).
3. Navigate to the path of your reference pdb file (use a pdb file that is generated from the explicit solvent minimized min2.rst file and strip off all water and ion molecules).
4. Execute *xleap* (this command assumes that \$AMBERHOME is defined and \$AMBERHOME/bin is added to your PATH).

```
$xleap -s -f $AMBERHOME/dat/leap/cmd/leaprc.ff99SB
```

5. Inside of the GUI, use the following commands.
 - a. Load any modification parameters that are necessary (an example for s²C is shown).

```
>loadamberprep 2SC.prepin  
>loadamberparams 2SC.frcmod
```

- b. Load the pdb file (ensure that the correct atoms are added, if not correct, you may need to go back and edit the pdb file to be more leap-friendly).

```
>model = loadpdb "XXX.pdb"
```

- c. Check the structure for problems including improper or missing bonds, unbounded atoms or distorted structure.

```
>edit model
```

- d. Neutralize the ASL with Na⁺ ions.

```
>addions model Na+ 0
```

- e. Solvate the molecule with explicit TIP3P water molecules in a truncated octahedral water box (the example is for a 10.0Å cutoff).

```
>solvateoct model TIP3PBOX 10.0
```

- i. Here, the value of 10.0 will most likely not give you the exact number of water molecules as that of the starting structure.
- ii. First optimize this by trying different values for the box cutoff and determining which value gives you the least amount of EXCESS water molecules.
- iii. Now, after you have added the water box, delete the excess water molecules using the following command to remove residue number 3654:

```
remove model model.3654
```

- f. Save the prmtop and inpcrd files.

```
>saveamberparm model XXX.prmtop XXX.inpcrd
```

E.3 Targeted Molecular Dynamics Simulation

For the targeted molecular dynamics simulations, you will need to optimize the force parameter and determine what length of time will be good for your simulations. For the example here, I will be using a weighting that will linearly decrease the target RMSD from 3.5Å (the initial is ~3.6Å) to 0Å over a time of 4ns. The simulation will then be left to run for an additional 1ns with the target RMSD set at 0Å.

6. Create the input file for the targeted molecular dynamics and give it a name (example: ACG-Ri_tgtmd.in).
 - a. Input file (example: ACG-Ri_tgtmd.in)

```

tgtrmsmask=":1-17 & !@H=" # Defines the atoms for calculation of
RMSD.

```

17. Execute the targeted MD simulation using the following command.

n. For serial targeted MD simulation:

```
$ sander -O -i ACG-Ri_tgtmd.in -o ACG-Ri_TMD.out -p ACG.prmtop -c  
ACG_So_P1.rst -r ACG-Ri_TMD.rst -x ACG-Ri_TMD.mdcrd -ref  
Rib_ACG.inpcrd
```

o. For parallel targeted MD simulation on the cluster (the `-N` flag denotes the number of nodes, `-n 8` denotes the number of processors, `-J` is for the name of the job on the cluster, `-p` to denote that a batch job is being used and `--wrap` is for the execution command) **NOTE:** The `-N` and `-n` flags can be adjusted. For instance the targeted MD simulations will require at least 8 processors to be efficient.

```
$sbatch -N 1 -n 8 -J ACG -p batch --wrap="mpirun -np 8 sander.MPI -  
O -i ACG-Ri_tgtmd.in -o ACG-Ri_TMD.out -p ACG.prmtop -c  
ACG_So_P1.rst -r ACG-Ri_TMD.rst -x ACG-Ri_TMD.mdcrd -ref  
Rib_ACG.inpcrd"
```

p. Parallel simulations can be monitored using the command: `$squeue`

7. Targeted MD simulations can be analyzed using ptraj as described for standard MD simulations (Appendix D8).

APPENDIX F – The RNA modification database, RNAMDB: 2011 update

William A. Cantara, Pamela F. Crain, Jef Rozenski, James A. McCloskey, Kimberly A. Harris, Xiaonong Zhang, Franck A. P. Vendeix, Daniele Fabris, Paul F. Agris

Published in Nucleic Acids Research, 2011, Vol. 39 (Database issue), p. D195-201.

F.1 Statement of Project Contribution

This project was solely the responsibility of me. While other authors were instrumental in teaching me the history of the database, how to understand the flow of the database programming architecture and for migration of the database onto University at Albany servers, I wrote the paper, designed the tables and figures and assisted with the development of the database as a highly customizable template for future upgrading into a web portal. With the help of Leslie Zuker and Andrew Wright, my contribution to this project continues with the design and implementation of the most up-to-date version of the database (<http://mods.rna.albany.edu/>) that includes new functionality: updated references with direct links to primary literature, updated text and acknowledgements, improved search and content management functionality and enhanced graphics.

F.2 Abstract

Since its inception in 1994, *The RNA Modification Database* (RNAMDB, <http://rnadb.cas.albany.edu/RNAmods/>) has served as a focal point for information pertaining to naturally occurring RNA modifications. In its current state, the database employs an easy-to-use, searchable interface for obtaining detailed data on the 109 currently known RNA

modifications. Each entry provides the chemical structure, common name and symbol, elemental composition and mass, CA registry numbers and index name, phylogenetic source, type of RNA species in which it is found, and references to the first reported structure determination and synthesis. Though newly transferred in its entirety to The RNA Institute, the RNAMDB continues to grow with two notable additions, agmatidine and 8-methyladenosine, appended in the past year. *The RNA Modification Database* is staying up-to-date with significant improvements being prepared for inclusion within the next year and the following year. The expanded future role of The RNA Modification Database will be to serve as a primary information portal for researchers across the entire spectrum of RNA-related research.

F.3 Introduction

The chemical composition of an RNA molecule allows for its inherent ability to play many roles within biological systems. This ability is further enhanced through the site selected addition of the 109 currently known post-transcriptional modifications catalyzed by specific RNA modification enzymes [1]. These naturally-occurring modifications are found in all three major RNA species (tRNA, mRNA and rRNA) in all three primary phylogenetic domains (archaea, bacteria and eukarya) as well as in a handful of other RNA species such as snRNA [2-5] (Table 1). The modifications are one of the most evolutionarily conserved properties of RNAs. Due in large part to comprehensive investigations into the structural and functional roles of modified nucleotides in tRNA, significant advancements have been achieved in our understanding of the various roles played by these modifications [2,6-9]. The need to provide a comprehensive, searchable database to house this wealth of knowledge led to the first iteration of *The RNA Modification Database* (RNAMDB) in 1994 [10]. The current version of the database, now housed at The RNA Institute at the University at Albany SUNY, contains all naturally-occurring, RNA-derived modified ribonucleosides for which the chemical structures are known. The RNAMDB provides a user-friendly, searchable interface that directs the user to a detailed information page for each database entry (Fig. 1).

Users are invited to submit comments regarding existing entries, including errors and omissions, as well as suggestions for improvements to the following email address: rnamdb@albany.edu.

F.4 Database Contents

A comprehensive introduction page provides a detailed overview of the current state of the RNAMDB, an in-depth description of the entries and a page specifically dedicated to modifications found in ribosomal RNA. The overview section of the introduction page provides a focus on commonly used symbols representing RNA modifications, reasons for exclusion of certain modified nucleosides and an extensive listing of reviews for further reference.

Presently, the information page for each RNAMDB entry contains the following details (Fig. 2a-g).

- a) Chemical structure of the modified nucleoside: this structure is simplistic and is not meant to imply the preferred orientation of dihedral angles or sugar pucker
- b) Common name and symbol
- c) The searchable Chemical Abstracts registry numbers and index name, which may provide stereochemical information not shown in the chemical structure
- d) Elemental composition and molecular weight
- e) Phylogenetic source of the RNA (ie. archaea, bacteria or eukarya) and the type of RNA species in which it is found (ie. tRNA, rRNA, etc.)
- f) Literature references for the first reported structure and synthesis. Reports of more recent synthesis or refinements can be found using the Chemical Abstracts registry numbers noted above

- g) Comments pertaining to any of the information provided on the entry information page provided by database curators

An example of a single entry information page for 2-methyladenosine has been provided (Fig. 2). The RNAMDB contains 109 such entries that consist of 93 found in tRNAs, 31 in rRNA, 13 in mRNA and 14 in other RNA species such as snRNA, snoRNA and miRNA [3,4,6] (Table 1).

In addition to the Introduction and Search pages, the website contains a compilation of links to other helpful databases and search tools, and provides access to a suite of programs designed to assist in the identification and characterization of nucleic acids by mass spectrometry (Masspec Toolbox). These dedicated programs are capable of calculating the mass of ribo- and deoxyribo-oligonucleotides from their sequence, as well as predicting the masses of products obtained by submitting a certain species to tandem mass spectrometry (MS/MS), or to digestion by endo- and exonucleases. Other tools can calculate nucleotide and elemental composition from a certain mass and provide the corresponding isotopic distribution. All of these tools allow for users to account for the presence of chemically modified nucleotide residues.

F.5 Recent Additions

Since the publication of the last database overview [3], fourteen new entries have been added to the RNAMDB, including agmatidine and 8-methyladenosine, which have both been added within the past year [11-25] (Table 2). Agmatidine (C^+) was recently found in archaeal AUA-decoding tRNA^{Ile2}, where it performs a function similar to lysidine, a modified cytidine residue containing lysine in place of the C2-oxo group, in bacteria [23]. In *E. coli*, the presence of lysidine at the first position of the anticodon allows for AUA-decoding tRNA^{Ile2} to recognize A and not G in the third position of the codon [26]. Agmatidine has a structure very similar to lysidine in which agmatine (decarboxy-arginine) replaces the C2-oxo group of cytidine (Fig. 3a) and, at the first position of the anticodon, performs the same function of

differentiating between A and G at the third position of the codon in *H. marismortui* [23]. The discrimination between A and G that results from the presence of lysidine or agmatidine is hypothesized to play an important role in the stabilization of potential positively charged tautomeric structures at neutral pH, which are able to selectively base pair with A [23].

Similar to 2-methyladenosine (m^2A) [27], 8-methyladenosine (m^8A , Fig. 3b) is present in the large subunit of bacterial ribosomes, specifically in the peptidyl transferase center at position A2503 of 23S rRNA as confirmed by comparison to the chemically synthesized mononucleoside [24]. Whereas the m^2A chemistry shows only a small amount of antibiotic resistance [28], the m^8A moiety confers extensive resistance to five major classes of peptidyl transferase-targeting antibiotics [29]. Interestingly, the m^8A mononucleoside was also synthesized in 1993 and shown to be a potent inhibitor of vaccinia virus [25]. This modification is a clear example of why it is important to understand the purpose of RNA modifications in living systems and how they can be utilized for therapeutic purposes. As an interesting side note, the presence of dimethylated A2503 (m^2m^8A) was also reported [24]; however, this modification has yet to be fully characterized or structurally confirmed.

F.6 The RNA Institute Takes Over as Curator

As of January 2009, upkeep and supervision of the RNAMDB has been turned over to The RNA Institute. Already, this transfer has resulted in a major layout makeover in May 2009 to match the theme of the newly established institute. As a part of its mission, The RNA Institute will be expected to become a proposed hub of cutting edge RNA research and a leading provider of structural and functional information in the field of RNA modifications. For this reason, The RNA Institute will provide the logical base for new enhancements aimed at expanding the focus of the current infrastructure to cover other important aspects of modern RNA research. These enhancements will be embodied by the proposed creation of a portal that will constitute a primary resource for researchers across the entire spectrum of RNA-related disciplines. The portal will not only include the current RNAMDB and

associated tools, but will also contain a collection of pertinent experimental protocols, fundamental information about RNA structure and function and additional informatics tools. From this new infrastructure, users will be able to access other informatics resources for RNA science, including different repositories of experimental protocols, force field parameters for molecular dynamics simulations [30], and sister databases dedicated to non-natural RNA modifications. The infrastructure for all of the above-mentioned improvements will be implemented on a rolling basis as they are completed during 2011. A full-featured RNA portal is a goal to be reached in 2012.

The experimental protocols made available by the RNAMDB portal will comprise established procedures that are common praxis in a typical RNA lab, but will also include new cutting-edge methods developed by the broader RNA community. The RNA Institute will be expected to play an important role in populating this section, due to the research interests of its members and the nature of their collaborations, which involve the development of enabling technologies based on a wide range of experimental approaches, including nuclear magnetic resonance, X-ray crystallography, single-molecule spectroscopy and, with the recent opening of The RNA Mass Spectrometry Center, high-resolution mass spectrometry. However, any investigator engaged in RNA research will be encouraged to share his/her favorite techniques with the broader RNA community through the portal. Any new protocol will require proof, either through publication in a peer-reviewed journal or empirical representative data that demonstrate its usefulness, effectiveness, and reproducibility. Links to other repositories of information on specific methods, such as peer-reviewed scientific journals, will allow users to conveniently access the most up-to-date and well-characterized methods in the literature. While it is important to note that this enhancement will take a great deal of time to populate in the next two years with useful protocols from the various disciplines within the RNA community, the initial steps for incorporation into the RNAMDB are currently in progress.

The proposed portal will be hosting a number of tools for predicting RNA secondary structure folding, the energy of those structures, and their predicted biophysical properties,

such as melting temperature. For instance, the popular RNA folding programs Mfold [31] and UNAFold [32] developed by Dr. Michael Zuker will soon be accessible through the current RNAMDB infrastructure and will be subsequently incorporated in the portal. Full integration will be achieved by making the information stored in the RNAMDB directly accessible by the folding algorithms in such a way as to enable users to calculate the possible effects of RNA modifications on energetics and structure stability. Since a drastic restructuring of the source code will be required, full integration of Dr. Zuker's folding programs will likely be implemented during the 2012-13 academic year; however, the programs are currently included, in their previous state, as a part of the RNAMDB. In a similar fashion, we plan on modifying existing software to enable the productive utilization of the information in the RNAMDB. For example, full integration with the programs in the existing Masspec Toolbox suite will greatly benefit the MS identification and characterization of natural RNAs extracted from living organisms. The new tools developed for the portal will be designed to take advantage of the information stored in the site and, thus, will be capable of accessing the different types of data and seamlessly communicating with one another across the board.

The proposed portal will include a constantly updated compilation of hyperlinks to external sources that may provide additional information for the identification and the structure-function investigation of RNA. In addition to repositories of experimental protocols, these links will direct users to pertinent peer-reviewed journals, *the RNA Society*, *the Transfer RNA Database* [33], *the Collaboratory for MS3D* [34], and many others. Links will also seamlessly point users to the external primary sources of information contained in the RNAMDB website. For instance, users will no longer be required to copy and paste the Chemical Abstracts registry numbers from the RNAMDB to the CAS Registry website. Instead, they will simply need to click on the hyperlinked CAS Registry number. Similarly, all references to both internal and external sources will be hyperlinked to provide quick access to all primary information. Additionally, it has become apparent that the information contained within the RNAMDB can be supplemented by cross-referencing with other relevant information residing in other databases such as *Modomics* [1] and *tRNADB* [33].

Other planned enhancements to the RNAMDB functionalities include incorporation and cross-referencing with new sister databases containing the growing amount of information on both natural and non-natural RNA modifications. A sister database of force field parameters for molecular dynamics simulations will also be included as a supplement to the newly incorporated table of modified nucleoside base pairing free energy (ΔG) minima [35]. Although excluded from the current RNAMDB, non-natural modifications are gaining increasing interest in both academic and corporate settings. These types of modifications include those used as research tools because of their ability to fluoresce [36], to restrict certain geometries, including backbone alterations [37], to enable unusual base pairing schemes [38] and to act as tools for probing structure [39,40]. Furthermore, other non-natural nucleosides that have been discovered as the products of interactions with pharmaceuticals and as a result of environmental stimuli will be also included.

Finally, it is becoming apparent that a more modern user interface will be needed to accommodate these new enhancements. With recent technological improvements, such as deep transcriptome analysis [41] and high-throughput mass spectrometry [42,43], which have led to advancements in our current understanding of RNA in biological systems, it has become necessary to create a more automated method for researchers to submit their findings to the RNAMDB for consideration. The new user interface is being developed for implementation during 2011 and will seek to create a more user-friendly experience while adding improved functionality. The new interface will allow the curators to dedicate more of their time and resources towards validating entries and developing new features. In this direction, while past iterations allowed for unpublished modifications to be included (Table 2), the new implementation and curating structure will require publication as a criterion for entry into the RNAMDB. This will create a benchmark for the inclusion of modifications that have been diligently characterized and will reduce the likelihood of inaccurate entries.

F.7 Availability

The RNA Modification Database is freely available to researchers via the web address, <http://rna-mdb.cas.albany.edu/RNAmods/>. Additionally, the programs contained in the Masspec Toolbox are also free for public use through the link on the database homepage and via the web address, <http://rna-mdb.cas.albany.edu/RNAmods/rnamass.htm>. Users of information contained within this database are requested to cite this article as their source of information.

F.8 Acknowledgements

The authors are grateful for the contributions of Phil Durant for the 3D graphic of yeast tRNA^{Phe} on the homepage and Patrick Limbach for his extensive work on the initial assembly and publication of the database. Additionally, we would like to thank Richard Walker, Steven Pomerantz and Byron Bossenbroek who contributed to the initial compilation of the database. The electronic version of the database was initially designed by Di He, Joe Zhang and Nancy Lombardo (University of Utah). Maintenance of the RNAMDB is supported by The RNA Institute at the University at Albany.

F.10 Tables and figures

Table F1. The RNA modifications in the database are present in all phylogenetic groups and in many of the known RNA species.

RNA	Phylogenetic Source		
	Archaea	Bacteria	Eukarya
tRNA	43	45	51
rRNA		1*	4*
SSU	11	8	18
LSU	8	15	12
5S	3		1
5.8S			5
mRNA			13
tmRNA		2	
snRNA			11
Chromosomal RNA			2
Other Small RNA			1

*Denotes rRNA modifications in which the subunit of origin is either unknown or reported as a mixture of subunits.

Table F2. Fourteen modifications have been added to the database since the last update was published in 1999.

Entry	Symbol	Common Name	Phylogenetic Source	RNA Type	Refs
96	m ¹ Gm	1,2'- <i>O</i> -dimethylguanosine	Archaea	tRNA	(11,12)
97	m ¹ Am	1,2'- <i>O</i> -dimethyladenosine	Eukarya	tRNA	(13,14)
98	tm ⁵ U	5-taurinomethyluridine	Eukarya	tRNA	(15,16)
99	tm ⁵ s ² U	5-taurinomethyl-2-thiouridine	Eukarya	tRNA	(15,16)
100	imG-14	4-demethylwyosine	Archaea	tRNA	(17,18)
101	imG2	isowyosine	Archaea	tRNA	(17)
102	ac ⁶ A	<i>N</i> ⁶ -acetyladenosine	Archaea	tRNA	(19,20)
103	inm ⁵ U	5-(isopentenylaminomethyl)uridine	Bacteria	tRNA	(21)
104	inm ⁵ s ² U	5-(isopentenylaminomethyl)- 2-thiouridine	Bacteria	tRNA	(21)
105	inm ⁵ Um	5-(isopentenylaminomethyl)-2'- <i>O</i> methyluridine	Bacteria	tRNA	(21)
106	m ^{2,7} Gm	<i>N</i> ² ,7,2'- <i>O</i> -trimethylguanosine	Archaea	tRNA	(21)
107	m ⁴ ₂ Cm	<i>N</i> ⁴ , <i>N</i> ⁴ ,2'- <i>O</i> -trimethylcytidine	Archaea	tRNA	(22)
108	C ⁺	agmatidine	Archaea	tRNA	(23)
109	m ⁸ A	8-methyladenosine	Bacteria	rRNA	(24,25)

2-methyladenosine

(b) **common name:**
2-methyladenosine

symbol:
m²A

CA index name:
Adenosine, 2-methyl-

(c) **CA registry numbers:**
ribonucleoside 16526-56-0
base 1445-08-5

elemental composition:
C₁₁H₁₅N₅O₄

(d) **nucleoside mass:**
281.27

(e)

RNA	phylogenetic source		
	archaea	bacteria	eukarya
trRNA	+	+	
rRNA		23S [1] 23S [2]	

(f) **Structure:** [3]

Synthesis: [4]

(g) **Comment:** Although ref [1] reports m²A to be in a mixture of SSU and LSU subunits, various more recent studies have shown that m²A is not present in the bacterial SSU (see [SSU database](#)) but is in the LSU [5].

Figure F2. The entry information page for 2-methyladenosine shows a typical representation of the statistics that is contained within the database.

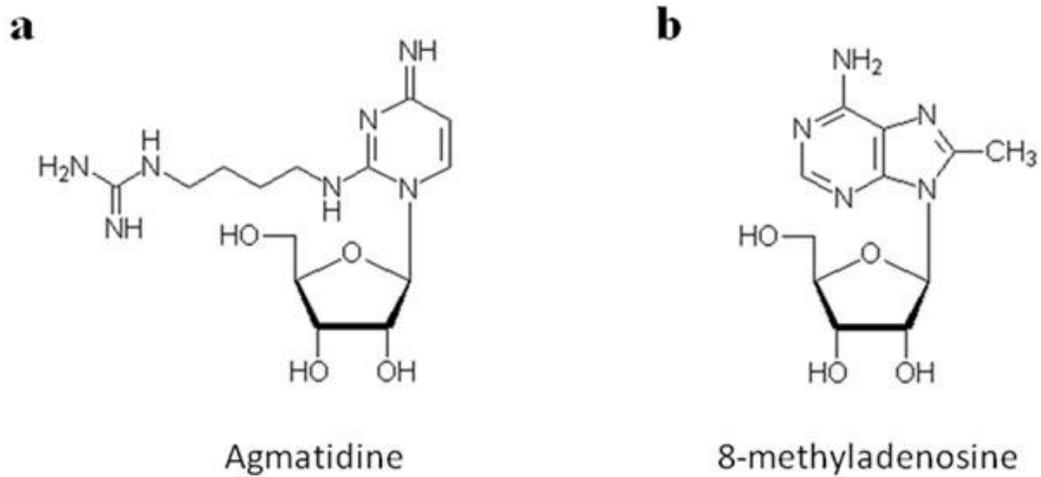

Figure F3. The two most recent additions to The RNA Modification Database, (a) agmatidine and (b) 8-methyladenosine, have been discovered and structurally characterized within the past year.

APPENDIX G. Curriculum vitae

G.1 Education

North Carolina State University, Raleigh, North Carolina, 2007-Present

- Ph.D. in Molecular and Structural Biochemistry (Spring 2012, expected)
- PI: Paul F. Agris
- **Research Topic:** Decipher the structural and functional roles of naturally-occurring posttranscriptional modifications in the anticodon stem and loop domain of the six-fold degenerate tRNA^{Arg} isoacceptors in *E.coli* using structural and biophysical characterization and functional codon binding assays.

Juniata College, Huntingdon, Pennsylvania, 2001-2005

- B.S. in Biochemistry and Physics, (2005)
- PI: Jill B. Keeney
- **Research Topic:** Examination of the mechanism of high temperature transposition of the endogenous Ty1 retroelement in *S.cerevisiae* using genetic approaches; analysis of the production of virus-like particle proteins using SELDI-TOF mass spectrometry.

G.2. Professional Experience

Conductive Technologies, Inc., York, Pennsylvania, 2006-2007

- Biosensor Scientist in the Research and Development Division
- **Research Topic:** Development of novel glucose biosensor formulation for increased sensitivity and performance, reduction of hematocrit bias and decrease in result time.

Croda Inc., Mill Hall, Pennsylvania, 2005-2006

- Quality Control Chemist in the QC/QA Department

Exygen Research Inc., State College, Pennsylvania, 2003

- Research Technician in Liquid Chromatography and Mass Spectrometry
- **Research Topic:** Analytical determination of synthetic chemical compounds present in biological matrices.

G.3. Teaching Experience

North Carolina State University

- Chemistry/Physics Tutor; Initiative for Maximizing Student Diversity (2009-2010)
- Teaching Assistant; Advanced Biochemistry Laboratory (2007)

North Carolina State University & University at Albany, SUNY

- Mentored one high school student and three undergraduate students (2007-Present)

G.4. Awards and Honors

- 2011 – American Society for Biochemistry and Molecular Biology Travel Award
- 2010 – The RNA Institute Travel Award
- 2010 – Department of Biological Sciences Travel Award
- 2009 – American Society for Biochemistry and Molecular Biology Travel Award
- 2008 – Samuel B. Tove Award for Outstanding Teaching
- 2004 – William J. von Liebig Summer Research Fellowship
- 2001 – 2005: Calvert Ellis Scholarship
- 2001 – 2005: Homer C. and Ethel F. Will Scholarship

G.5. Research Techniques

Handling and purification of RNA, DNA and protein:

- Preparative PAGE RNA purification (unlabeled and radiolabeled)
- Purification of DNA and molecular cloning
- Preparative HPLC of small RNA and DNA oligomers
- Recombinant protein expression and purification
- *In vitro* transcription
- Site-directed mutagenesis

Binding assays:

- Radioligand filter binding assays

- Electrophoretic mobility shift assays
- Fluorescence quenching assays
- Isothermal titration calorimetry

Biophysical and structural characterization of RNA:

- Thermal denaturation and circular dichroism spectroscopy
- Differential scanning calorimetry
- NMR: currently being trained to solve the structure of three 17-mer hairpin RNAs
- X-ray crystallography: currently being trained to solve structures of the bacterial ribosome with a 17-mer hairpin RNA bound in the A-site

Computational characterization of RNA:

- Implicit and explicit solvent, targeted molecular dynamics and umbrella sampling
- GPU accelerated molecular dynamics
 - Assisting with the setup of a GPU-based computing center at The RNA Institute
- Docking simulations of RNA with large chemical libraries of ligands
- Software: Linux OS, AMBER, Autodock, Vina, PyMol, VMD, Chimera, Grace, Phenix

Robotics for high throughput screening:

- Use of a Perkin Elmer Janus system for setup of high throughput assay development
