INVITED ARTICLE

An efficient procedure for the study of inhomogeneous liquids

F. Lado*

Department of Physics, North Carolina State University, Raleigh, NC 27695-8202, USA

(Received 20 October 2008; final version received 31 October 2008)

A complete description of an inhomogeneous fluid requires knowing not only its density \( \rho(r) \) at any point \( r \) in space, but also its pair distribution function \( g(r_1, r_2) \) describing the spatial correlation of two fluid particles at locations \( r_1 \) and \( r_2 \). By the definition of inhomogeneous, this latter quantity is no longer just a function of \( r_{12} = |r_1 - r_2| \) and therein lies the special challenge of solving Ornstein–Zernike (OZ) type integral equations for such systems. In many cases, the symmetry of a specific system will allow the general inhomogeneous OZ equation [1],

\[
h(r_1, r_2) = c(r_1, r_2) + \int dr_3 h(r_1, r_3) \rho(r_3) c(r_3, r_2),
\]

(1)

to be partially deconvoluted using an integral transform, leaving a final one-dimensional integral unevaluated. (Here \( h(r_1, r_2) = g(r_1, r_2) - 1 \) is the inhomogeneous pair correlation function and \( c(r_1, r_2) \) the inhomogeneous direct correlation function effectively defined by the OZ equation.) Written in discrete form on a finite grid with summation replacing integration, this final equation for the transforms can then be interpreted as a matrix problem in direct space and solved accordingly. This usually entails a large number of spatial grid points and so the inhomogeneous liquid problem has acquired a reputation as computationally intensive (by integral equation standards, leaving aside simulation). In this note, for the Festschrift on the occasion of Jean-Jacques Weis’ retirement, we describe how the remaining integral can also be analytically evaluated and the OZ equation reduced to an algebraic relation among expansion coefficients alone, just as for homogeneous molecular liquids, with an attendant sharp reduction in computing effort. This simplification is accomplished by the construction of tailored functions designed to be orthogonal with weight function \( \rho(r) \).

The inhomogeneous OZ equation, coupled with an exact relation between the one-body and two-body functions (described below), was first solved for fluids in contact with a single hard wall by Sokolowski [2,3] and by Plischke and Henderson [4,5]. Liquids between two parallel walls (a planar slit) have been extensively and elegantly studied by Kjellander and Sarman [6–9]. These works all use a Hankel transform to eliminate two of the three integrals in the inhomogeneous OZ equation. Attard [10] has shown how the two angular integrals can be eliminated using a Legendre transformation for fluids with spherical inhomogeneity. A clever application is then created by letting the spherical inhomogeneity arise from a fluid particle fixed at the origin of coordinates, so that an \( n \)-body distribution function in the inhomogeneous liquid becomes an \( (n+1) \)-body distribution function in the original homogeneous system. Familiar approximations now made at the nominal two-body level produce far better results [11–14] than when made at the conventional two-body level in a homogeneous formulation.

2. Reducing the OZ equation to algebra

A planar slit of width \( L \) is allowed to have indefinite wall extent so no boundary conditions are needed in the plane of the walls. The inhomogeneity then occurs perpendicular to the wall planes, which we denote conventionally as the \( z \) direction. The density is now a one-dimensional function, \( \rho(z) \), and pair functions such as \( h(r_1, r_2) \) can be described using coordinates \( R_{12} \equiv [(x_1 - x_2)^2 + (y_1 - y_2)^2]^{1/2} \), \( z_1 \), and \( z_2 \); thus, \( h(r_1, r_2) = h(R_{12}, z_1, z_2) \), etc. The OZ equation now reads

\[
\begin{align*}
\hat{h}(R_{12}, z_1, z_2) & = c(R_{12}, z_1, z_2) + \int_{L/2}^{L/2} \frac{dz_3}{\Delta z} \rho(z_3) \\
& \times \int dR_3 h(R_{13}, z_1, z_3)c(R_{32}, z_3, z_2). 
\end{align*}
\]

The first step in simplifying this equation is to use the homogeneity of the pair functions in the \( R \) plane to deconvolute it with a Hankel transform [2–9]:

\[
\hat{h}(K, z_1, z_2) = \int dR \ h(R, z_1, z_2)e^{-iKR} = 2\pi \int_{0}^{\infty} dR \ h(R, z_1, z_2)J_0(KR),
\]

\[
\big(2\pi\big)^{-1} \int_{0}^{\infty} \int dK \hat{h}(K, z_1, z_2)e^{iKR} = \frac{1}{2\pi} \int_{0}^{\infty} dK \hat{h}(K, z_1, z_2)J_0(KR),
\]

where \( J_0(x) \) is the Bessel function of order zero. We then obtain

\[
\hat{h}(K, z_1, z_2) = \hat{c}(K, z_1, z_2)
\]

\[
+ \int_{L/2}^{L/2} \frac{dz_3}{\Delta z} \rho(z_3)\hat{h}(K, z_1, z_3)\hat{c}(K, z_3, z_2),
\]

with one remaining integral. This is the version of the OZ equation that all earlier papers have used. In practice, of course, the equation must be solved on a finite grid of points on the \( z \) axis. If we use \( N_z \) points, their spacing is \( \Delta z = L/(N_z - 1) \) and the discrete version is

\[
\hat{h}_j(K) = \hat{c}_j(K) + \sum_{k=-N_z/2}^{N_z/2} \Delta z \rho_k \hat{h}_k(K)\hat{c}_j(K),
\]

where \( \rho_j = \rho(z_j) \). \( \hat{h}_j(K) = \hat{h}(K, z_1, z_j) \), etc., with \( z_j = j \Delta z \). A more symmetric version of the equation can be obtained by multiplying through with \( (\rho_j\rho_k)^{1/2} \). In any case, one now has a matrix equation that can be manipulated using standard matrix techniques. Since a large number of grid points is generally needed for an accurate numerical representation, the result is a calculation that is often deemed to be ‘computationally intensive’.

The usual remedy for this sort of problem is an expansion of the \( z \) dependence in orthogonal functions, with the critical expectation that far fewer expansion coefficients will be needed than grid points on the \( z \) axis. Here that would ordinarily mean expansions in plane waves (using periodic boundary conditions),

\[
E_m(z) \equiv e^{im(2\pi z/L)} = T_m[\cos(2\pi z/L)] + iV_m[\sin(2\pi z/L)],
\]

where \( m \) is a positive or negative integer. (For brevity, we will put

\[
\xi \equiv \cos(2\pi z/L)
\]

in the remainder of this work.) We recognize here \( T_m(\xi) = \cos[m(2\pi z/L)] \) as the type I Chebyshev polynomial of order \( m \) and \( V_m(\xi) = \sin[m(2\pi z/L)] \) the associated Chebyshev function (not a polynomial) of order \( m \) [15]. The familiar exponential functions \( E_m(z) \) of course have the orthonormalization

\[
\frac{1}{L} \int_{-L/2}^{L/2} dz \ E_m(z)E_{m'}(z) = \delta_{mm'},
\]

where the asterisk denotes complex conjugate, for \( m, m' \) positive or negative integers. But if we now put into Equation (5)

\[
\hat{h}(K, z_1, z_3) = \sum_{m_1, m} \hat{H}_{m_1 m}(K)E_{m_1}(z_1)E_{m}^{*}(z_3),
\]

and similarly for \( \hat{c}(K, z_3, z_2) \), the integral that turns up is not Equation (9), but rather

\[
\frac{1}{L} \int_{-L/2}^{L/2} dz \ \rho(z)E_m(z)E_{m'}^{*}(z),
\]

and the invaluable property of orthogonality is lost.

The essential proposal of this work is that one should simply replace the familiar \( E_m(z) \) with specially
constructed basis functions $\mathcal{E}_m(z)$ that are specifically designed to be orthogonal with weight function $\rho(z)$. Preferring a dimensionless weight function, we define the mean density

$$\tilde{\rho} = \frac{1}{L} \int_{-L/2}^{L/2} dz \, \rho(z),$$

and put $\rho(z) = \tilde{\rho} f(z)$. Then the tailored orthogonal functions will be constructed to satisfy

$$\frac{1}{L} \int_{-L/2}^{L/2} dz f(z) \mathcal{E}_m(z) \mathcal{E}^*_{m'}(z) = \delta_{mm'},$$

again for $m, m'$ positive or negative integers, while $f(z)$ itself is normalized to unity,

$$\frac{1}{L} \int_{-L/2}^{L/2} dz f(z) = 1.$$ 

Now we may put

$$\hat{h}(K, z_1, z_2) = \sum_{m_1, m_2 = -\infty}^{\infty} \hat{h}_{m_1 m_2}(K) \mathcal{E}_{m_1}(z_1) \mathcal{E}^*_{m_2}(z_2),$$

and similarly for $\hat{c}(K, z_1, z_2)$, so that the OZ equation finally becomes a relation among expansion coefficients alone,

$$\hat{h}_{m_1 m_2}(K) = \hat{c}_{m_1 m_2}(K) + \tilde{\rho} L \sum_{m_1, m_2 = -\infty}^{\infty} \hat{h}_{m_1 m_2}(K) \hat{c}_{m_1 m_2}(K).$$

We note that coefficients of all pair functions satisfy the symmetries

$$\hat{c}_{m_1 m_2}(K) = \hat{c}_{m_2 m_1}(K) = \hat{c}_{m_1 m_2}(K) = \hat{c}_{m_2 m_1}(K),$$

where $m \equiv -m$. As usual, it is numerically preferable to eliminate $h$ from the OZ equation and solve instead for the continuous 'series' function [16] $s = h - c$, for which we obtain

$$\hat{s}_{m_1 m_2}(K) = \tilde{\rho} L \sum_{m_1, m_2 = -\infty}^{\infty} [\hat{s}_{m_1 m_2}(K) + \hat{c}_{m_1 m_2}(K)] \hat{c}_{m_1 m_2}(K).$$

This is finally solved for the $\hat{s}_{m_1 m_2}(K)$; in matrix notation,

$$\hat{S}(K) = \tilde{\rho} L \hat{C}(K) \hat{C}(K) \hat{C}(K) \hat{C}(K)[I - \tilde{\rho} L \hat{C}(K)]^{-1},$$

where $\hat{S}(K)$ and $\hat{C}(K)$ are square matrices with elements $\hat{s}_{m_1 m_2}(K)$ and $\hat{c}_{m_1 m_2}(K)$, respectively, and $I$ is the unit matrix. (Given the symmetries (16), only one-quarter of the elements of $\hat{C}(K)$, etc., are unique.) The notable feature of Equation (18) is that it is identical to that of a homogeneous system. All of the inhomogeneity is built into the basis functions.

The construction of the tailored basis functions $\mathcal{E}_m(z)$,

$$\mathcal{E}_m(z) = \mathcal{T}_m(z) + i\mathcal{V}_m(z),$$

for $m \geq 0$, where $\mathcal{T}_m(z)$ and $\mathcal{V}_m(z)$ are the needed generalized Chebyshev functions, is outlined in Section 4. We turn first to the relationship between $\rho(z)$ and the pair functions.

### 3. Calculating the density profile

There are three exact equations that connect the one-body and two-body functions. Triezenberg and Zwanzig [17], Lovett et al. [18], and Wertheim [19] have shown that

$$\frac{d \ln \rho(z_1)}{dz_1} = -\frac{d \beta v_{\text{ext}}(z_1)}{dz_1} \int_{-L/2}^{L/2} dz_2 \rho(z_2)$$

$$\times \int dr \, h(R_{12}, z_1, z_2) \frac{d \beta v_{\text{ext}}(z_2)}{dz_2}$$

$$= -\frac{d \beta v_{\text{ext}}(z_2)}{dz_2} \int_{-L/2}^{L/2} dz_2 \rho(z_2) \hat{h}(0, z_1, z_2)$$

$$\times \frac{d \beta v_{\text{ext}}(z_2)}{dz_2},$$

where $v_{\text{ext}}(z)$ is the external potential (here the walls of the planar slit) and $\beta = (k_B T)^{-1}$ the inverse Kelvin temperature, with $k_B$ Boltzmann’s constant. Alternatively, passing through the OZ equation, this can be written as

$$\frac{d \ln \rho(z_1)}{dz_1} = -\frac{d \beta v_{\text{ext}}(z_1)}{dz_1} + \int_{-L/2}^{L/2} dz_2 \rho(z_2)$$

$$\times \int dr \, c(R_{12}, z_1, z_2) \frac{d \rho(z_2)}{dz_2}$$

$$= -\frac{d \beta v_{\text{ext}}(z_1)}{dz_1} + \int_{-L/2}^{L/2} dz_2 \rho(z_2) \hat{c}(0, z_1, z_2)$$

$$\times \frac{d \ln \rho(z_2)}{dz_2}.$$
smoother and continuous combination \( f(z) \exp[\beta_{\text{ext}}(z)] \). We work first with Equation (21) and put

\[
\ln[f(z)e^{\beta_{\text{ext}}(z)}] = \sum_{m=0}^{\infty} A_m T_m(\xi), \tag{23}
\]

\[
\hat{h}(0, z_1, z_2) = \sum_{m_1, m_2} \hat{h}_{m_1 m_2}(0) E_{m_1}(z_1) E_{m_2}^*(z_2). \tag{24}
\]

where we now seek to calculate the coefficients \( A_{mn} \).

(Note that \( A_0 \) is determined by normalization.) We have for Equation (21),

\[
\sum_{m=1}^{\infty} \frac{dT_m(\xi)}{dz} = -\sum_{m_1, m_2=1}^{\infty} \tilde{p}\hat{h}_{m_1 m_2}(0) E_{m_1}(z)
\]

\[
\times \int_{-L/2}^{L/2} dz' f(z') E_{m_2}^*(z') \frac{d\beta_{\text{ext}}(z')}{dz'}. \tag{25}
\]

Now multiply this equation by \((i/L)f(z)E_{m'}^*(z)\) and integrate over \( z \). Then again invoking the orthonormality integral, Equation (12), we arrive at the simple matrix equation

\[
\sum_{m=1}^{\infty} D_{m'n'} A_m = H_{n'}. \tag{26}
\]

Here we have defined

\[
D_{m'n'} = \frac{2}{L} \int_0^{L/2} dz f(z) V_m(\xi) \frac{dT_m(\xi)}{dz}, \tag{27}
\]

\[
H_{n'} = -\tilde{p}L \sum_{m=1}^{\infty} [\hat{h}_{m m}(0) - \hat{h}_{m m}(0)] \frac{2}{L}
\]

\[
\times \int_{-L/2}^{L/2} dz f(z) V_m(\xi) \frac{d\beta_{\text{ext}}(z)}{dz}, \tag{28}
\]

and have used symmetry to simplify the integrals and the summation in Equation (28). A final matrix inversion in Equation (26) yields the coefficients \( A_m \) for the logarithm of the density profile.

Equation (22) works out in a similar fashion, with an extra matrix multiplication at the end. Since we have \( f(z) \exp[\beta_{\text{ext}}(z)] \) as our objective, we first add and subtract \( \beta_{\text{ext}}(z_2) \) under the derivative \( d/dz_2 \) on the right-hand side of (22). This gives

\[
\frac{d}{dz_2}\ln[f(z_1)e^{\beta_{\text{ext}}(z_1)}]
\]

\[
= \tilde{p} \int_{-L/2}^{L/2} dz_2 f(z_2) \tilde{c}(0, z_1, z_2)
\]

\[
\times \frac{d}{dz_2}\ln[f(z_2)e^{\beta_{\text{ext}}(z_2)}]
\]

\[
- \tilde{p} \int_{-L/2}^{L/2} dz_2 f(z_2) \tilde{c}(0, z_1, z_2) \frac{d\beta_{\text{ext}}(z_2)}{dz_2}. \tag{29}
\]

Again expanding functions as in Equations (23) and (24), we now have

\[
\sum_{m=1}^{\infty} A_m \frac{dT_m(\xi)}{dz} = \sum_{m=1}^{\infty} \sum_{m_2=1}^{\infty} \tilde{p}\hat{c}_{m_1 m_2}(0) A_m E_{m_1}(z)
\]

\[
\times \int_{-L/2}^{L/2} dz' f(z') E_{m_2}(z') \frac{dT_m(\xi)}{dz'}
\]

\[
- \sum_{m_1, m_2} \hat{c}_{m_1 m_2}(0) E_{m_1}(z)
\]

\[
\times \int_{-L/2}^{L/2} dz' f(z') E_{m_2}^*(z') \frac{d\beta_{\text{ext}}(z')}{dz'}. \tag{30}
\]

which we once more follow with a multiplication by \((i/L)f(z)E_{m'}^*(z)\) and integration over \( z \). This yields

\[
\sum_{m=1}^{\infty} \sum_{m'} \left[ \delta_{m'm'} - \tilde{p}L \hat{c}_{m'm'}(0) \right] D_{m'm} A_m
\]

\[
= -\sum_{m'=1}^{\infty} \tilde{p} \hat{c}_{m'm'}(0) \int_{-L/2}^{L/2} dz f(z) V_{m'}(\xi) \frac{d\beta_{\text{ext}}(z)}{dz}. \tag{31}
\]

Now put

\[
Q_{m'm} = \sum_{m'=1}^{\infty} \left[ \delta_{m'm'} - \tilde{p}L \hat{c}_{m'm'}(0) \right] D_{m'm} \tag{32}
\]

\[
C_{m'} = -\tilde{p}L \sum_{m=1}^{\infty} \hat{c}_{m'm}(0) \frac{2}{L}
\]

\[
\times \int_{-L/2}^{L/2} dz f(z) V_{m}(\xi) \frac{d\beta_{\text{ext}}(z)}{dz}, \tag{33}
\]

so that the \( A_m \) are again found by a simple matrix inversion, now of

\[
\sum_{m=1}^{\infty} Q_{m'm} A_m = C_{m'}. \tag{34}
\]

Using the OZ Equation (15), one can show that Equations (26) and (34) are identical. Calculating the \( A_m \) separately from both could be useful as an internal numerical check.

4. Constructing the orthogonal functions

The familiar procedure for constructing a new set of orthogonal functions from a given complete set is the Gram–Schmidt method [15]. Thus, starting with the standard polynomials \( T_m(\xi) = \cos[m(2\pi z)/L] \), the first three (unnormalized) new polynomials of \( \xi \) that are orthogonal with weight function \( f(z) \) can be explicitly written as

\[
\rho_0(\xi) = 1, \tag{35}
\]
\[ p_1(\xi) = T_1(\xi) - \mu_1 p_0(\xi), \]  
\[ p_2(\xi) = T_2(\xi) - \left( \frac{\mu_2 - 2\mu_1 + \mu_1}{2\mu_1 + 1} \right) p_1(\xi) - \mu_2 p_0(\xi), \]  
for \( k = 1, \ldots, n - 1 \) and \( j = k, \ldots, 2n - k - 1 \). We set \( a_0 = a_0 + v_f^j/v_f^j \) and \( b_0 = 0 \); then putting \( \sigma_{k+1,k-1} = 0 \) and \( \sigma_{k,k} = 0 \) yields, respectively,
\[ b_k = \frac{\sigma_{kk}}{\sigma_{k-1,k-1}} , \]  
\[ a_k = \alpha_k + \frac{\sigma_{k,k+1}}{\sigma_{kk}} - \frac{\sigma_{k-1,k}}{\sigma_{k-1,k-1}} , \]  
for \( k = 1, \ldots, n - 1 \), and the \( n \) monic polynomials \( P_1(\xi), \ldots, P_n(\xi) \) are determined by recursion, Equation (41).

A final normalization yields the desired generalized Chebyshev polynomials,
\[ T_0(\xi) = 1, \]  
\[ T_m(\xi) = \frac{P_m(\xi)}{[2(P_m | P_m)]^{1/2}}, \ m = 1, \ldots, n. \]  
The algorithm further generates the roots \( \xi_1, \xi_2, \ldots, \xi_n \) of \( T_n(\xi) = 0 \) and the weights \( w_j \) for the \( n \)-point Gauss–Chebyshev quadrature,
\[ \frac{2}{L} \int_0^{L/2} dz f(z) F(\xi) \approx \sum_{j=1}^n w_j F(\xi). \]  

The quadrature is exact if \( F(\xi) \) is a polynomial of degree less than or equal to \( 2n - 1 \), such as in Equation (27).

A similar procedure can now be followed for the generalization \( U_m(\xi) \) of type II Chebyshev polynomials \( U_m(\xi) \) [15]. For this we need the corresponding monic coefficients, \( a_m^U = 0 \) and \( b_m^U = 1/4 \), for all \( m \), and the modified moments
\[ v_f^j = 2 \int_0^{L/2} dz f(z) \sin^2(2\pi z/L) \frac{U_j(\xi)}{2} . \]  
It is easy to show that
\[ v_f^j = 1/2 - v_f^j, \]  
\[ v_f^j = v_f^j/4 - v_f^{j+2}, \]  
for \( j > 0 \).

The construction of the \( U_m(\xi) \), normalized to \( 1/2 \) with weight function \( f(z) \sin^2(2\pi z/L) \), then follows precisely that of the \( T_m(\xi) \), so we finally get the desired \( V_m(\xi) = \sin(2\pi z/L)U_m(\xi) \).

By construction, then, these generalized Chebyshev functions \( T_m(\xi) \) and \( V_m(\xi) \) satisfy
\[ \frac{1}{L} \int_{-L/2}^{L/2} dz f(z) T_m(\xi) T_{m'}(\xi) = \begin{cases} 1, & m = m', \\ 1/2, & m = m' \not= 0, \\ 0, & m \not= m'. \end{cases} \]
Collectively, Equations (50)–(52) give rise to the orthonormalization of $E_m(z)$ expressed in Equation (12).

5. An illustration

In this section, we illustrate some practical details regarding the formal tailored polynomials discussed above. As noted earlier, actual applications will be left to later work.

For purposes of illustration we choose a system of hard spheres of diameter $\sigma$ between parallel hard walls a distance $L$ apart [6,9]. The external potential is then

$$\beta\nu_{\text{ext}}(z) = \begin{cases} 0, & |z| \leq (L - \sigma)/2, \\ \infty, & (L - \sigma)/2 < |z| \leq L/2, \end{cases}$$

(53)

so that the initial (non-interacting) density profile of the system is

$$f(z) = L \frac{L - \sigma}{L - \sigma} H\left(\frac{L - \sigma}{2} + z\right) H\left(\frac{L - \sigma}{2} - z\right),$$

(54)

where $H(x)$ is the Heaviside unit step function and the prefactor is chosen for normalization, Equation (13). In this case, we can calculate the needed $v_j^T = (2/L) f_0^{L/2} dz f(z) \pi_j(\xi)$ analytically. We obtain

$$v_0^T = 1,$$

(55)

and the appropriate $T_m[\cos(2\pi z/L)]$ are then constructed following the recipe in Section 4.

We have arbitrarily chosen $L = 5\sigma$ for these calculations and show in Figure 1 the first four special polynomials $T_1(\xi), \ldots, T_4(\xi)$ generated for this case (omitting the trivial $T_0(\xi) = 1$). They are seen to be quite changed from the original constant-amplitude Chebyshev form, $T_m(\xi) = \cos[m(2\pi z/L)]$. Similarly, the corresponding first four generalizations of $V_m(\xi) = \sin[m(2\pi z/L)]$, $V_1(\xi), \ldots, V_4(\xi)$, seen in Figure 2, also display variable amplitudes, though of course they still vanish at the end points. Note that the integral common to both Equation (28) and (33) picks up the values of these latter functions at the cutoff, $z = (L - \sigma)/2$:

$$\frac{2}{L} \int_0^{L/2} dz f(z) V_m(\xi) \frac{d\beta\nu_{\text{ext}}(z)}{dz} = -\frac{2}{L} \int_0^{L/2} dz f(z) e^{\beta\nu_{\text{ext}}(z)} V_m(\xi) \frac{d\beta\nu_{\text{ext}}(z)}{dz}$$

$$= \frac{2}{L} \int_0^{L/2} dz f(z) e^{\beta\nu_{\text{ext}}(z)} V_m(\xi) \delta\left(z - \frac{L - \sigma}{2}\right)$$

$$= \frac{2}{L - \sigma} V_m\left[\cos\left(\frac{L - \sigma}{L}\right)\right].$$

(57)

It is clear from the earlier sections that the procedure proposed here at least yields a satisfying simplification of the formalism used to solve the prescribed equations for a full description of an inhomogeneous fluid. The practical question, however, is whether it
also produces a significant reduction in computing time for these solutions, perhaps even putting such calculations on a par with those of homogeneous systems. This is essentially a question of how the number of coefficients, say \( n \), used in an expansion like (23) compares with the number of grid points, say \( N_z \), needed for an equally good representation of the same function directly on the \( z \) axis. In a real calculation, Equation (23) would be used to find \( \ln[\tilde{f}(z) \exp[\beta v_{\text{ext}}(z)]] \) from the calculated \( A_m \). Here we are going to turn that around, create a realistic model of a continuous density profile on the \( z \) grid, and see how many coefficients \( A_m \) are required to reproduce it.

For the modeled density profile we turn to the Percus–Yevick (PY) equation for hard spheres [20]. Specifically, we start with the continuous function \( g_{\text{HS}}(r) \exp[\beta v_{\text{HS}}(r)] \) that the PY equation produces at \( \rho \sigma^3 = 0.8 \) with a grid interval \( \Delta r = 0.02\sigma \), cut out the section from \( r = 0.5\sigma \) to \( r = 3.0\sigma \), and call that the left half of our modeled density profile, \( f_0(z) \exp[\beta v_{\text{ext}}(z)] \), over the interval \( z = -2.5\sigma \) to \( z = 2.5\sigma \) with \( \Delta z = 0.02\sigma \). Then we simply fold that piece over to produce the symmetric right half; the result is shown in Figure 3. This continuous density profile is not a very familiar quantity. If, however, we now truncate this shape at \( \pm(L - \sigma)/2 \) (that is, multiply by \( \exp[-\beta v_{\text{ext}}(z)] \)), we get the discontinuous density profile \( f_d(z) \) seen in Figure 4. This is indeed a familiar quantity. Specifically, it strongly resembles (by design) the density profile computed by Kjellander and Sarman [9] for hard spheres between hard walls at separation \( L = 5\sigma \) and shown as their Figure 1(c). Thus, the data for Figure 3 will serve as our realistic test profile. It is based on \( N_z = 250 \) grid points; we then use fourth-order interpolation to obtain the test density profile at the \( n \) points needed for the Gauss–Chebyshev quadrature below.

Applying the expansion of (23) to our test profile, we have

\[
\ln[f_0(z) e^{\beta v_{\text{ext}}(z)}] = \sum_{m=0}^{n-1} A_m T_m(\xi), \tag{58}
\]

where we are still using the special polynomials \( T_m(\xi) \) constructed for the \( f(z) \) of Equation (54) and sampled in Figure 1. Thus, multiplying this equation by \( (1/L) f(z) T_k(\xi) \) and integrating over \( z \) produces, for \( k > 0 \),

\[
A_k = \frac{2}{L} \int_{-L/2}^{L/2} \, dz f(z) \ln[f_0(z) e^{\beta v_{\text{ext}}(z)}] T_k(\xi) = 2 \sum_{j=1}^{n} w_j \ln[f_0(z) e^{\beta v_{\text{ext}}(z)}] T_k(\xi), \tag{59}
\]

after invoking Equations (50) and (47). The quadrature is now evaluated for successive values of \( k \); the results are shown graphically as \( A_m \) vs. \( m \) in Figure 5, for which we have used \( n = 30 \). It seems clear that, holding \( n \) fixed at 30, fewer than the 30 coefficients \( A_m \) (numbered 0 through 29) seen in the figure would actually suffice in the expansion (58). In fact, we anticipate that the cutoff limits for single index expansions such as (23) or double index expansions such as (14) may be set at some integer \( n_c \) that is meaningfully smaller than the given \( n \), which is kept larger to set the parameters for the Gauss–Chebyshev quadratures.

We conclude that the number \( n_c \) of coefficients needed in the tailored orthogonal functions procedure put forward in this work will be about an order of magnitude smaller than the number of grid points \( N_z \) needed for the direct space procedures used in earlier works. Since much of the numerical effort involves...
matrix operations, of order $N^2$ in Equation (6) vs. $n^2$ in Equation (15), we may reasonably conclude that solutions obtained using the tailored orthogonal functions will require on the order of 1% of the computational effort of those earlier works. That should make equations for inhomogeneous fluids as readily solvable as their more familiar homogeneous cousins.

[16] M.S. Green, J. Chem. Phys. 33, 1403 (1960); *ibid* 39, 1367 (1963). Green classified the diagrams in the density expansion of $g(r) e^{i\theta(r)}$ by analogy with electric circuits as ‘series’, ‘parallel’, or ‘bridge’, the last because of the resemblance of the first diagram to a Wheatstone bridge. The ‘parallel’ terms can be summed in direct space and disappear. The name ‘series’ is nowadays seldom used but the ‘bridge’ name incongruously survives.
