ABSTRACT

The lifetime extension of the nuclear power stations is considered as an energy challenge worldwide. That is why, the risk analysis and the study of various effects of different factors that could potentially represent a hazard to a safe long term operation are necessary. These structures, often of great dimensions, are subjected during their life to complex loading combining varying mechanical loads, multiaxial, with non-zero mean values associated with temperature fluctuations and also PWR environment.

Historically, the methodology for fatigue dimensions of the Pressurized Water Reactor components (PWR) (ASME, RCC-M, KTA, ...) is based on the use of design curves established from tests carried out in air at 20°C on smooth specimens by integrating safety coefficients that cover, among other parameters, the dispersion of tests associated with the effects of structures.

Based on more recent fatigue data (including tests at 300°C in air and PWR environment, etc...), some international codes (RCC-M, ASME and others) have proposed and suggested a modification of the austenitic stainless steels fatigue curve combined with a calculation of an environmental penalty factor, namely Fen, which has to be multiplied by the usual fatigue usage factor.

The aim of this paper is to present a new device "FABIME2E" developed in the LISN in collaboration with EDF and AREVA. These new tests allow quantifying accurately the effect of PWR environment on semi-structure specimen. This new device combines the structural effect like equi-biaxiality and mean strain and the environmental penalty effect with the use of PWR environment during the fatigue tests.

INTRODUCTION

The question of assessing the margins and safety factors in the fatigue analyses which are widely used today (ASME BPV III, RCC-M, JSME, EN-13445-3, etc... Chopra O.K. and Shack W.J. (2007), RCC-M (2007), EN-13445-3 V1 standard (2014), RCC-MRx (2012)) is a very challenging one.

The fatigue rules used today in the nuclear industry were initially built and integrated into the ASME code in the 1960's. Establishing fatigue rules is a challenge in itself since fatigue degradation depends on the wear of components which undergo repeated cycling: fatigue tests can therefore be very long and costly, if led on full-size components. As a result, the testing is in practice conducted on small laboratory specimens, which then triggers the question of how to extrapolate results to a full size component. Another difficulty is that the rules need to remain easy to apply in order to be applied for industrial engineering calculations. Since 2007, the USA with the NUREG/CR-6909 Chopra O.K. and Shack W.J. (2007), have now included the evaluation of environmental effects in their official regulation. Indeed, on the curves

presented in Figure 1 and Figure 2, the PWR water environment effect on the fatigue lifetime of material used in the manufacture of reactor components are illustrated.

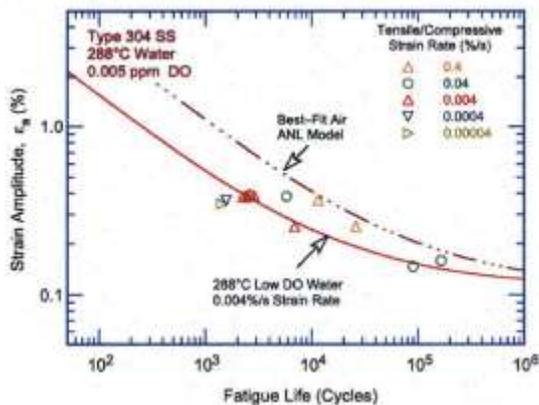

Figure 1. Fatigue life of 304L steel in PWR water compared with the ANL model Air curve

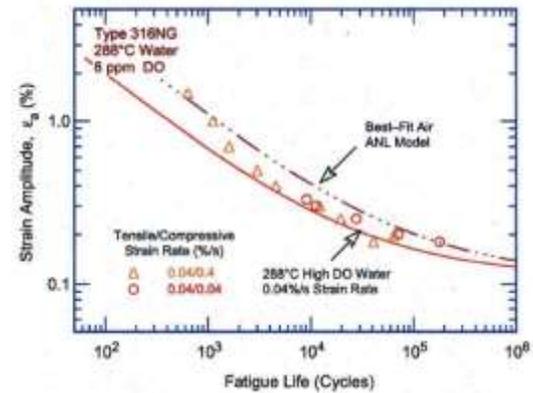

Figure 2. Fatigue life of 316L steel in PWR water compared with the ANL model Air curve

The 304L and the 316L stainless steel are used for the manufacturing of the pressurized water reactors (PWR). Many components of this type of reactors are subjected to a multiaxial thermo-mechanical cycling Fissolo A. et al. (2009) and De Baglion L. (2006). Therefore, the multiaxial fatigue assisted by environment is considered as one of the main degradation mechanisms affecting the life of the PWR components.

Based on more recent fatigue data (including tests at 300°C in air and PWR environment, etc...), some international codes (RCC-M, ASME and others) have proposed and suggested a modification of the austenitic stainless steels fatigue curve combined with a calculation of an environmental penalty factor, namely F_{en} , which has to be multiplied by the usual fatigue usage factor.

Unfortunately, there is no sufficient experimental data available concerning fatigue strength for the austenitic stainless steels subjected to structural loadings Lefebvre D.F. (1989), Itoh T. and al. (2006), Parsons, M. W. Et Pascoe, K. J. (1975), Shimada H. and al. (1976), Poncelet M. and al. (2010), which are used for power plants components. In order to obtain fatigue strength data under structural loading, biaxial test means with and without PWR environment were developed at LISN Bradaï S., and al. (2013), Bradaï S., and al. (2014), Bradaï S., and al. (2015).

Two kinds of fatigue device have been developed. Within the same specimen geometry, structural loads can be applied in varying only the PWR environment.

The first device (FABIME2) is devoted to study the effect of biaxiality and mean strain/stress on the fatigue life. A second and new device based on FABIME2 is for the study of the impact of the environmental effect. With these new experimental results, we will highlight a PWR effect on the fatigue life of stainless austenitic steels.

The FIRST experimental device

The objective of this first fatigue test was to dissociate the effect of the mean stress and equibiaxial state loading. Indeed, we try to obtain a negative load ratio in order to get the same results as the uniaxial data and eliminate the residual strain.

In this study, equibiaxial state loading generated from fatigue has been considered. It was used to optimize the geometry of a disk specimen refined in its center. It was used as a circumferentially embedded diaphragm with an applied pressure on both sides in order to obtain an equivalent strain in each loading direction in the plane (Figure 3).

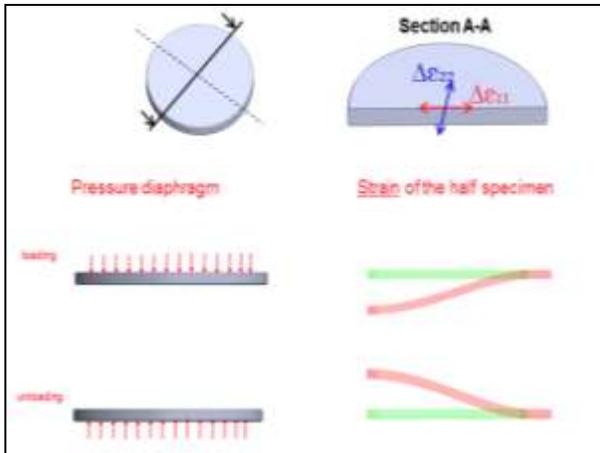

Figure 3. Principle of the first fatigue test

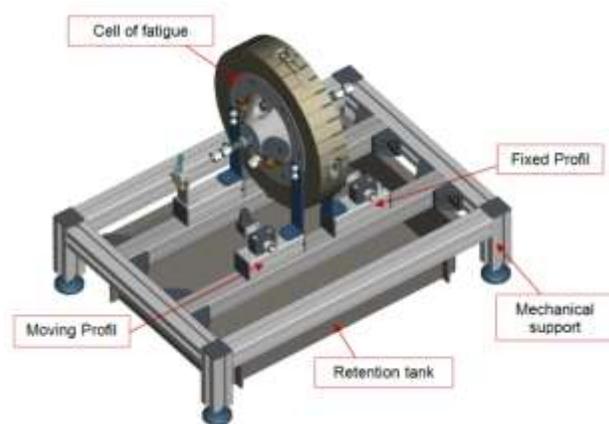

Figure 4. View of the spherical bending device: fatigue cell

The experimental device called « FABIME2 » is divided into four parts:

- Fatigue cell which contains the spherical bending specimen (cf. Figure 4),
- Pressure generating system until 100 bars,
- Electrical enclosure,
- Homemade software developed under LABVIEW that provides control and acquisition data during the tests.

Two half-shells allow the positioning of the spherical bending specimen. Seal and embedment are realized by bolting these two parts.

Maximum experimental conditions are 100 bars for the pressure and 90°C for the temperature. An alternative differential pressure between the two sides of the spherical specimen is applied during the fatigue test.

To ensure well-defined experimental conditions, various measuring means are located symmetrically at the two half-shells

- Pressure sensor with a measuring range between 0 to 100 bars
- Type K thermocouple to measure the temperature of the fluid inside the fatigue cell
- Displacement sensor (LVDT) to measure the deflection at the center of the spherical bending specimen. This sensor has a 5mm range. Realizations of surface observations after the fatigue test show that the contact between LVDT and specimen is negligible (no fretting). No crack initiation is also observed directly under the LVDT.
- Two visualization windows on each half-shell, oriented at 45° with a diameter of 20 mm. The constitutive material is borosilicate glass with a permissible operating pressure of 100 bars.

The fatigue cell was built under European Security directives (Machines 2006/42/CE, Pressure 97/23/CE).

The experimental results [15]

Biaxial fatigue tests were carried out on two austenitic stainless steels: “316L THY”, and “304L CLI”. The first material has been provided by Thyssen Krupp Materials France as a 15mm thickness rolled sheet. The second material supplied by EDF is characterized by a thickness of 30 mm rolled sheet.

The first fatigue test campaign was performed on austenitic stainless steel type 316L. Five levels of deflection were studied: 1.6 / 1.4 / 1.2 / 1.1 and 0.9 mm.

In the frame of CEA-EDF-AREVA working group, a second fatigue test campaign was performed on austenitic stainless steel 304-CLI provided by EDF. This material completely agrees with the RCC-M

(2007) and RCC-MRx (2012) specification. Four levels of deflection were carried out 1.4 / 1.3 1.2 and 1.1 mm.

Interpretation of the experimental results

We present an interpretation of the equibiaxial fatigue tests with the definition of the equivalent strain used in the nuclear industry. This is an important step to evaluate the impact of an equibiaxial loading on the fatigue life. All tests performed in this study are carried out with imposed displacement (strain) with alternating load (without mean stress or strain), means with a stress ratio $R=-1$.

To compare the experimental data obtained from uniaxial and equibiaxial tests, it is necessary to define a total equivalent strain.

Two definitions of equivalent strain are proposed: the first is based on the definition of von Mises (used in the RCC-MRx) and the second on the definition of TRESCA (used in the RCC-M, RSE-M).

Thus, the first equivalent strain used is the von Mises equivalent strain defined by the following equation:

$$\Delta \varepsilon_{eq}^{VM} = \sqrt{\frac{1}{1+\nu'} (\dot{\Delta \varepsilon} : \dot{\Delta \varepsilon})} = \frac{2(1+\nu')}{3(1-\nu')} \Delta \varepsilon_1 \quad (1)$$

with the strain deviatoric component:

$$\dot{\Delta \varepsilon} = \Delta \varepsilon - \frac{1}{3} \text{tr}(\Delta \varepsilon),$$

with ε_1 the principal strain and ν' the “real” Poisson’s ratio (elastic $\nu=0.3$ and plastic part $\nu=0.5$).

The second equivalent strain is the Tresca equivalent strain defined by the following equation:

$$\Delta \varepsilon_{eq}^T = \frac{1}{1+\nu'} \text{Max} |\varepsilon_i - \varepsilon_j| \quad (2)$$

The proposal approach to determine the level of the equivalent strain for each FABIME2 test is as follows:

- Determination of the value of the radial strain corresponding to the imposed deflection from the strain-deflection calibration curve obtained in the previous part of this paper. With a similar mechanical behavior, the calibration curve can be used for the two materials (Fig. 6a).
- Determination of the von Mises or TRESCA equivalent strain from the relation between the radial strain and the equivalent strain (von Mises or TRESCA). This relation has been determined by elasto-plastic calculation of the fatigue test. Theses elastic-plastic behavior computations are used to determine the “real” value of the Poisson’s ratio by taking into account the elastic and plastic part. In our case, the Poisson’s ratio is 0.415 for the largest deflection test (± 1.63 mm) and 0.396 for the lower deflection test (± 0.9 mm).

This method has been applied to the equi-biaxial fatigue tests presented earlier. The corresponding fatigue life curves are compared to that under uniaxial loading in Figure 5. It appears that there is also no impact of equi-biaxial fatigue for the two types of materials, considering von Mises equivalent strains.

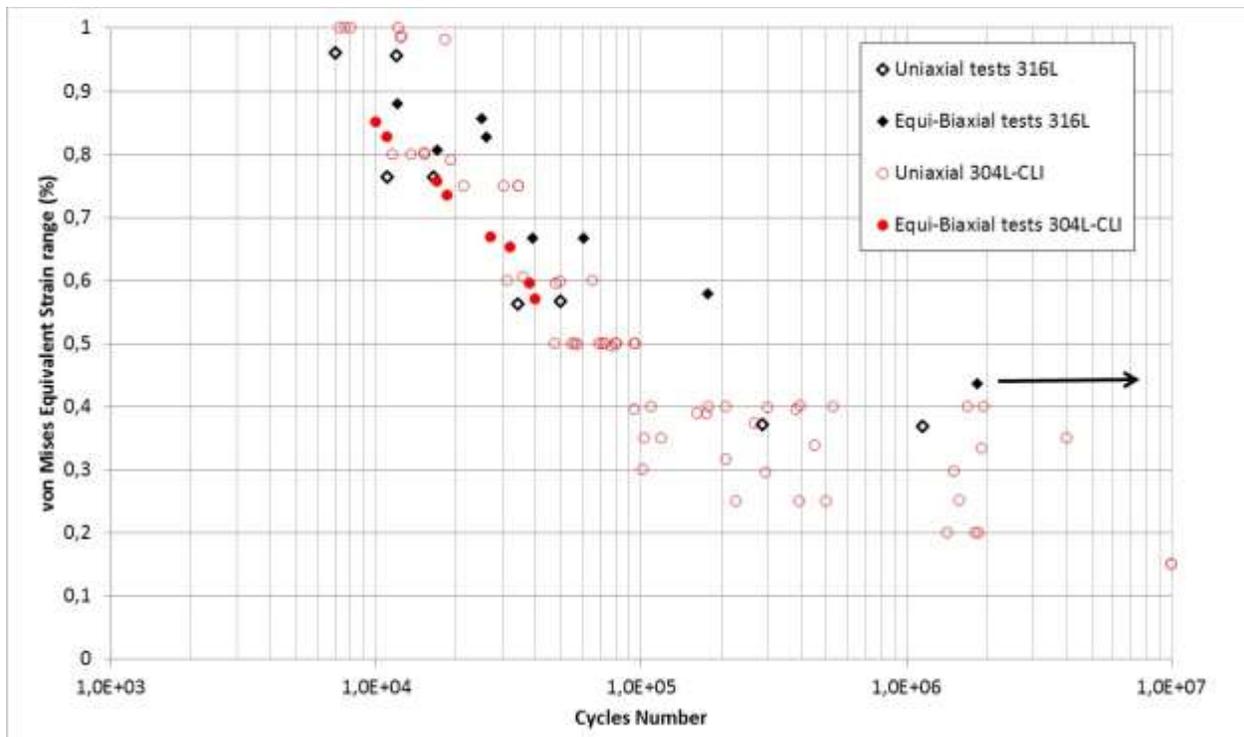

Figure 5. Fatigue data obtained on the two austenitic stainless steels (316L and 304L-CL1)

SPECIFICATION OF THE NEW DEVICE FABIME2E

The second fatigue device (FABIME2E, E for environment) has been developed to apply on the same specimen geometry the same structural loads in varying only the PWR environment.

Compared to FABIME2, specification changes for FABIME2E device mainly focused on the following points:

- Specimen is in contact with a PWR environment,
- An operating temperature of 340 °C,
- A maximum pressure up to 350 bar,
- Monitoring and adjustment of dissolved hydrogen level during testing,
- A perfectly flat and reproductive clamping of the specimen.

With these severe experimental conditions, four major technical difficulties had to be taken into account:

- The cohabitation of the PWR environment with the hydraulic oil at room temperature and 100 bar maximum,
- The PWR environment temperature stability: variations less than 1 °C up to several weeks should be allowed in order to detect the initiation of cracks,
- Monitor and adjust if necessary dissolved hydrogen level,
- The perfect sealing of the device during the tests.

A double cylinder system has been proposed to separate PWR and hydraulic fluids to apply a mechanical solicitation to the specimen (Figure 6). A double acting cylinder would be moved by the hydraulic unit. Its movement would be mechanically transmitted (by the water incompressibility) to a primary cylinder to modify the volume of the PWR environment contained in each half-shell. Similarly to FABIME2 this system applies a differential pressure, up to 100 bars, to the specimen. The difference here is that the pressure variation around the specimen is between 150 and 350 bar, respectively the biphasic threshold of the PWR environment and the maximum pressure allowed by FABIME2E.

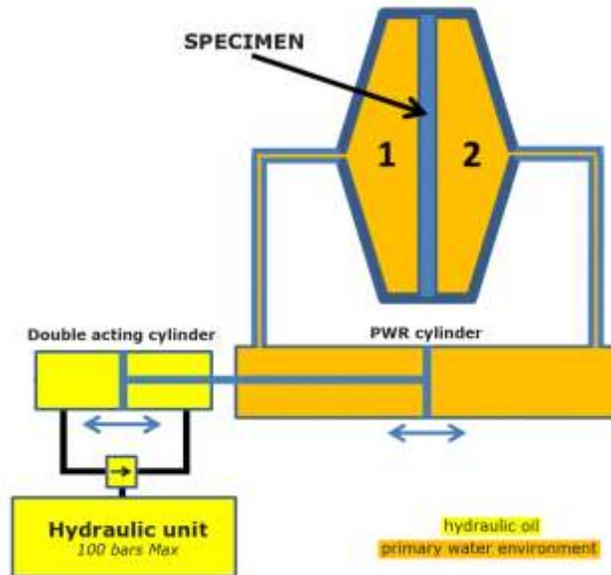

Figure 6: Double cylinder system for separation of PWR and Hydraulic fluid

If the required pressure in the PWR environment is obtained by its constraint thermal dilation, this phenomenon must be avoided during the test. A variation of 1 °C would cause a variation of several bars around the specimen. These pressure fluctuations may compromise the detection of the initiation of cracks by compliance. A stronger fluctuation could even lead the PWR environment under its biphasic threshold. This would require a test stop. To avoid this, a temperature regulation system with a great stability was required.

The evolution of the chemical composition of the environment was one of the concerns for this new bench. Hydrogen is the most volatile part of this, so the ability to measure and if necessary adjust its level was needed.

In the end, the requested instrumentation would enable the monitoring of the evolution of the following data, for each half-shell: temperature, pressure, displacement and dissolved hydrogen level.

The NEW experimental device: FABIME2E

The realization of FABIME2E was entrusted to French company TOP INDUSTRY. The maximum experimental conditions of the new device are 350 bar and 340 ° C.

The main organs of this new device are:

- A cell consisting of two half shells for holding the specimen,
- A clamping system for the cell,
- A sealing system compatible with the PWR environment,
- A closed PWR environment circuit,
- A « double cylinder » system to apply the mechanical solicitations on the specimen,
- An accurate and reliable heating system,
- A system for measuring and adjusting the level of dissolved hydrogen in the PWR environment,

Instrumentation for temperature, pressure, displacement.

Figure 7. View of the fatigue new bending device
FABIME2E

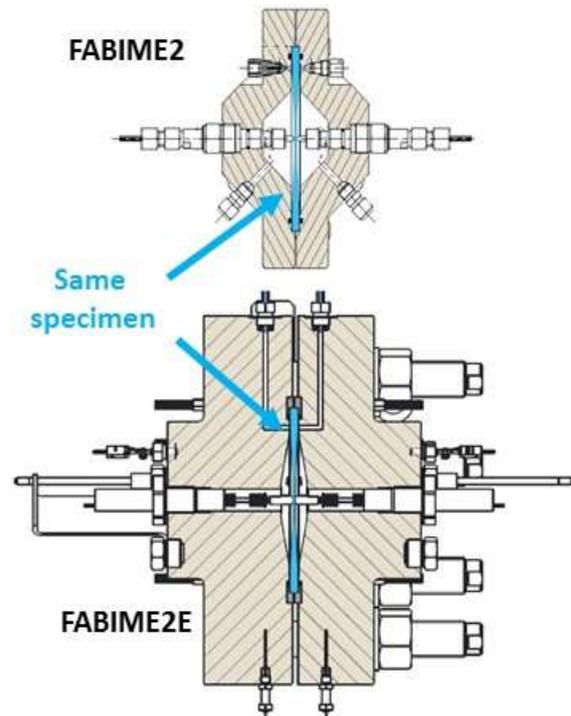

Figure 8. Comparison between FABIME2 and
FABIME2E fatigue cells (same scale and
specimen geometry)

Because of much higher pressures and temperatures, the FABIME2E cell has more imposing dimensions than its predecessor FABIME2 (Figure 8). However, the specimen geometry remains absolutely identical to be usable indifferently on the both test benches.

Technical specifications

Each half- shell has the following instrumentation:

- Two type K thermocouples, positioned at the top and bottom,
- A pressure sensor with a 0-400 bar range,
- A LVDT compatible with the PWR environment, with a ± 5 mm range to measure the deflection of the specimen,
- Two hydrogen sensors Pd -Ag from AREVA: one for measuring and one for adjusting the dissolved hydrogen level if necessary.

Two metal rings are disposed on each side of the specimen to ensure the sealing of the cell during the test period. Clamping is achieved by means of a hydraulic clamp machine to ensure flatness, sealing and repeatability. Height heavy section attachment studs ensure the two half shells clamping around the specimen.

FABIME2E cell has a 100 ml volume. After filling the cell and high-pressure pipes the heating achieves the desired pressure because of the thwarted thermal dilation of the primary water.

Eight cartridge heaters with an output of 250W each are located on each half-shell to reach the nominal temperature of 340 ° C. The temperature rise is carried out at a maximum rate of 1 ° C / min. The maximum

allowable temperature is 400 °C. Although the primary cylinder is at room temperature, a part of the pipes which connects it to each half-shell is also temperature controlled. Two EUROTHERM controllers (NANODAC model) ensure the regulation of the 4 heating zones.

The same hydraulic group provides oil to both FABIME2 and FABIME2E test benches.

As shown in Figure 6, a hydraulic cylinder allows transmitting loadings to the primary cylinder to deform the specimen.

As it is possible to do with the bench FABIME2, pressure, displacement or strain control is allowed. The development of the control software in the CEA laboratory allows great flexibility: cycling shape, holds, control mode modifications, mean pressure or strain.

The low-level tasks such as security management, hydraulic control and data reading require determinism and speed of processing. That is the reasons why they are devolved to real-time autonomous software running on a COMPACT RIO device (NATIONAL INSTRUMENT).

The tests management, acquisition and data analysis are performed by software running on a conventional PC. This second software controls each test sequence: from the filling of the PWR fluid till the crack initiation estimation through sending orders to the CRIO software and the EUROTHERM controllers.

FIRST TESTS CAMPAIGN (WITH HIGH PRESSURE AND AMBIENT TEMPERATURE)

A first series of test was carried out with the FABIME2E device. One of the objectives of these tests was the validation of the concept of the stages separation (oil / primary water) via the intermediate cylinder. The second objective was to demonstrate the criterion for detecting a crack initiation in the center of the specimen.

This series consists of five tests. The experimental conditions are: an initial pressure of 175 bar, an ambient temperature (30 ° C.) and an imposed deflection of 1.3 mm and 1.2 mm. The principle of detection of fatigue crack initiation is achieved by studying the evolution of the pressure applied to the fluid via the intermediate cylinder to obtain the imposed deflection of 1.3mm or 1.2mm. When a "significant" change in this pressure is observed. The test is stopped, the test piece is take off and observed. The crack initiation criterion is defined as having a crack length of 5 mm at the surface (see figure. 9), which corresponds to a (downward) variation in the pressure of the order of 1 to 2 bar.

A test was carried out in an interrupted manner, once a crack initiation was detected, the specimen was subjected to 500 cycles and the evolution of the crack size was observed (see figure. 10).

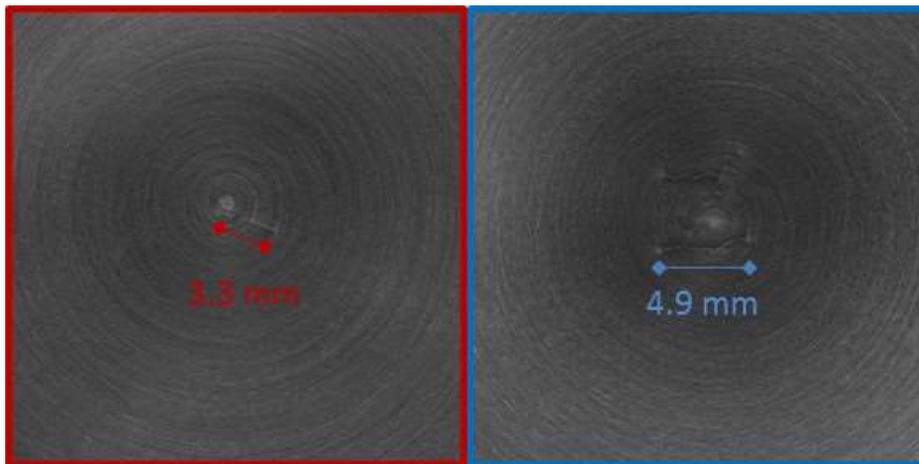

Figure 9. View of the fatigue crack initiation when the pressure criterion is goal.

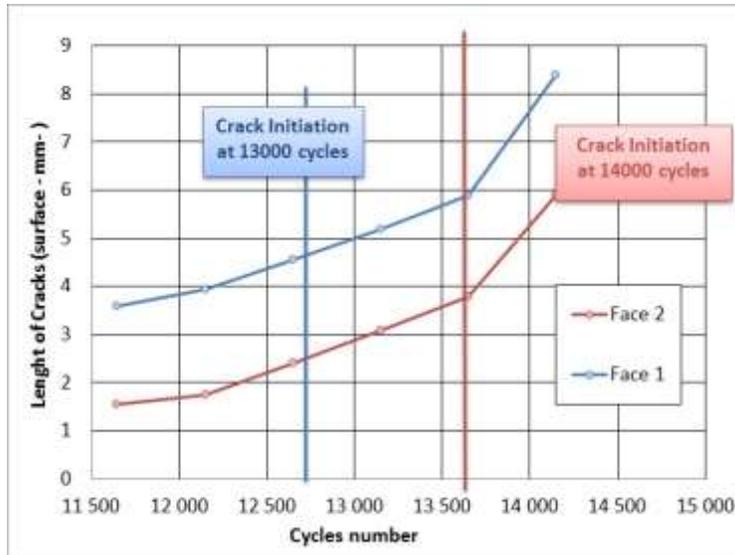

Figure 10. Crack length evolution for FABIME2E tests (175 bar, T=30°C, Δf=1.3 mm)

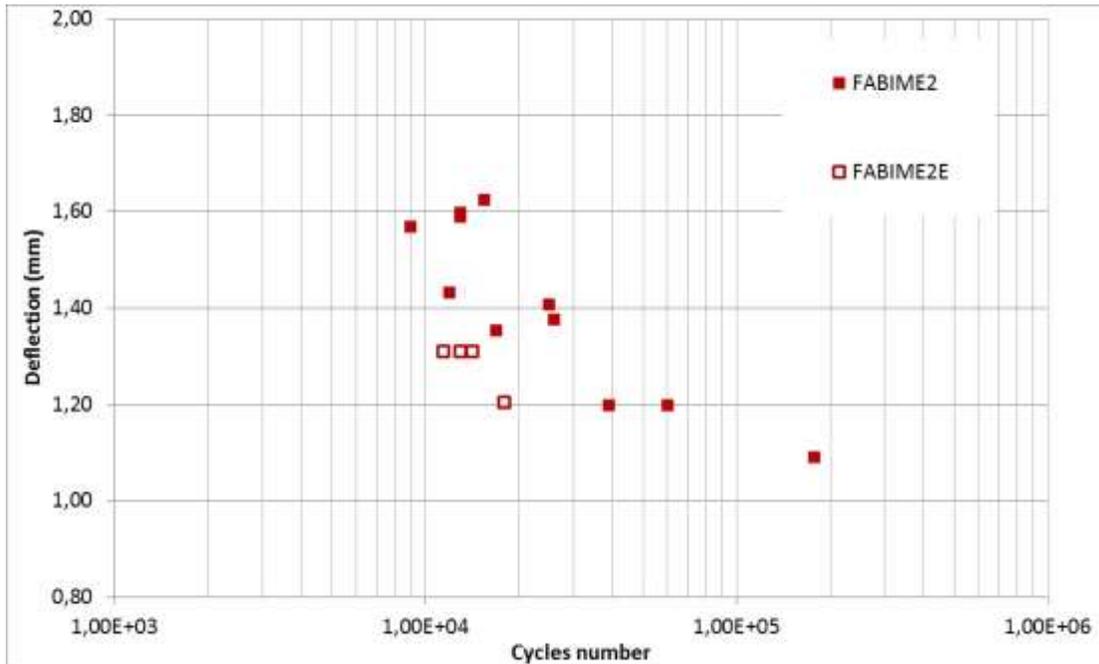

Figure 11. Fatigue data (imposed deflection) obtained on the austenitic stainless steel (316L) with and without high pressure water environment

Except the first test which devoted to validate the load-control home-made software. Four tests were carried out with a controlled deflection and the lifetime of all these tests under a pseudo-PWR environment (pressure water at 175 bar with ambient temperature 30°C) is divided by a factor of 2 compared to the same tests carried out on the FABIME2 device (in oil), see Figure 11.

CONCLUSION

This paper is focusing on the description of two kinds of experimental devices to perform fatigue tests on “structural” specimen with or without the effect of PWR environment.

The first device (FABIME2) is devoted to study the effect of biaxiality and mean strain/stress on the fatigue life. Biaxial fatigue tests are carried out on two austenitic stainless steels: 316L THY and 304L CLI. The results obtained show that crack initiation have a low impact on the fatigue life, which remains in the field covered by the design curve defined and used in the codification.

A second and new device based on FABIME2 is under development for the study of the impact of the environmental effect. This device will study the impact of the equibiaxial loadings with a primary water environment PWR (300°C with a permanent pressure of 140 bars). The first experimental tests validate the concept of this device (FABIME2E).

ACKNOWLEDGEMENTS

F. Datcharry and M. Rousseau from CEA is very greatly acknowledged for his participation in the FABIME2E conception.
